Estimates of the prevalence of OSA in the general population are variable and dependent on several factors, including the characteristics of the population studied (e.g., obesity, ethnicity), methods used to measure SDB, disease definitions (e.g., hypopnea definition), and the AHI threshold used to define OSA.[25,124,125] In the United States, a landmark community-based population study (the Wisconsin Sleep Cohort Study) published in 1993 reported the prevalence of OSA with daytime sleepiness (i.e., OSAS) to be 4% in men and 2% in women between the ages of 30 and 60.[126] In fact, current prevalence is likely to be substantially higher, given rising rates of obesity and the aging of the population worldwide.[127] The current prevalence estimate of moderate to severe sleep-disordered breathing (apnea–hypopnea index, measured as events/h, ≥15) is estimated at 10% of the adult U.S. population.[127]

A recent analysis utilizing available objective population prevalence data and data on BMI, race, age, and sex distributions in different countries estimated the worldwide number of adults between 30 and 69 years with OSA to be nearly 1 billion, with 425 million (>45%) individuals likely to have moderate or severe OSA.[128] It is important to recognize that the prevalence of OSA defined by the presence of SDB events alone, without daytime symptoms, is considerably higher than the prevalence of symptomatic OSA with excessive sleepiness.[25,126,129] For instance, 24% of men and 9% of women in the Wisconsin Sleep Cohort Study had an AHI of at least 5 events/h.[126] While the impact of milder, asymptomatic OSA on adverse health outcomes remains an area of active debate, recent evidence suggests that increased cardiovascular risk among those with OSA is strongly associated with the presence of daytime sleepiness.[130,131]

Age

The effect of age on the prevalence of OSA is complex. Population studies have demonstrated that the prevalence of OSA increases through midlife but then plateaus after age 60 to 65.[132] Furthermore, after controlling for obesity, mean OSA severity may decline with age.[25] Nevertheless, individuals between ages 65 and 100 are more than six times more likely to have OSA compared with men and women 20 to 44 years of age.[25,133] Several studies have observed that the prevalence of SDB is greater than 50% in those at least 65 years of age.[124,132,134] BMI is, however, less related to SDB in the older individuals. These findings have raised questions about whether there is a "survivor effect" for OSA among older adults (i.e., whereby those with OSA who survive to old age are relatively resistant to its adverse effects). Thus, the clinical significance of OSA in the elderly is debated, as is whether a higher threshold should be used to define OSA in this age group.[135,136]

Gender

Epidemiologic studies demonstrate that the prevalence of OSA is two to three times higher in men than women and that postmenopausal women are at an approximately threefold higher risk for OSA compared with premenopausal women.[25,126,137,138] The lower risk among premenopausal women appears to be related to the effects of reproductive hormones; however, data describing how hormone levels affect upper airway anatomy and function or the control of breathing leading to SDB remain limited.[139–141]

Gender differences in the prevalence of OSA may also be related to differences in body fat distribution. Men exhibit a more central fat distribution, including the neck, thereby increasing the risk for narrowing and closure of the upper airway.[142–144] Among women, pregnancy poses an additional period of vulnerability for SDB.[790] The prevalence of gestational sleep apnea has been estimated to be 3.6% in early pregnancy (6–15 weeks of gestation) and 8.3% during mid-pregnancy (22–31 weeks) in a large cohort of nulliparous women in a multicenter study.[145] Gestational sleep apnea is associated with important potential consequences for maternal and fetal well-being including greater risks for preeclampsia, hypertensive disorders of pregnancy and especially gestational diabetes.[145,146] A randomized trial of CPAP therapy in women with gestational sleep apnea (the CPAP for Sleep Apnea in Pregnancy [SLEEP] study) is currently being conducted by the NIH (*clinicaltrials.gov/ct2/show/NCT03487185*) to determine whether treatment reduces risks for hypertensive disorders of pregnancy.

Ethnicity

While most population-based prevalence estimates for OSA are derived from White populations, a number of recent studies have sought to characterize the burden of OSA in several Asian countries, in South America (Brazil), and among Blacks and Hispanics in the United States.[147–150] In Hong Kong, India, and Korea, the prevalence of OSA is similar to White population samples, despite the lower prevalence of obesity among Asians. In fact, after controlling the effects of age and obesity, OSA severity appears to be higher among Asians, perhaps due in part to craniofacial characteristics. In a study that matched Caucasian and Chinese patients for OSA severity, Chinese patients had more craniofacial bony restriction based on cephalometry.[151]

Among middle-aged Blacks, the prevalence of OSA is comparable to that in Whites.[132,152] A higher prevalence of OSA has been observed, however, among young Blacks (<25 years of age) compared with either Whites or Blacks in other age groups.[152,153] Data from a multiethnic study of the distribution of sleep-disordered breathing across a cohort of 2230 White, Black, Hispanic, and Chinese participants revealed that Hispanics were 2.14 times more likely to have severe SDB compared with Whites, confirming prior data suggesting a higher prevalence of OSA among Hispanics than non-Hispanic Whites.[154–157] Similarly, Chinese in this cohort study were 37% more likely to have severe SDB compared with Whites.[154]

■ Risk Factors for Sleep Apnea

Risk factors for OSA are summarized in Table 98-1.

Obesity

Worldwide, the prevalence of obesity has doubled in more than 70 countries since 1980 and has continuously increased in most other countries.[158] In the United States, by 2030, obesity prevalence is likely to approach 50% of the adult population.[159] The increase in obesity prevalence is important because numerous epidemiologic studies have shown that obesity is the strongest risk factor for OSA in adults, and that a dose–response relationship exists between excess body weight and sleep apnea prevalence, such that the prevalence of OSA is greatest among individuals in the highest BMI categories.[25,129,133,137,147–149,160] Although the majority of these investigations were cross-sectional, several longitudinal studies have demonstrated that weight gain accelerates disease progression.[161,162]

TABLE 98-1 Risk Factors for Obstructive Sleep Apnea

Obesity (BMI >30 kg/m^2)
Neck size (collar size >17 inches in males, >16 inches in females)
Gender (male/female 2–3:1)
Genetic factors/family history
Upper airway and craniofacial anatomy
Macroglossia
Lateral peritonsillar narrowing
Elongation/enlargement of the soft palate
Tonsillar hypertrophy
Nasal septal deviation
Retrognathia, micrognathia
Narrowing of the hard palate
Class III/IV modified Mallampati airway
Specific genetic disorders, e.g., Treacher Collins, Down syndrome, Apert syndrome
Endocrine disorders, e.g., hypothyroidism, polycystic ovarian syndrome, acromegaly
Alcohol, sedative, or hypnotic use

Interestingly, among the elderly, the influence of obesity is diminished compared to its effect in younger adults,[132] which may be due to accelerated mortality among obese individuals with OSA (i.e., survivorship bias) and the greater role of other age-related risk factors for OSA.

Individuals with OSA have been observed to have larger neck circumferences than those without.[53] Imaging studies have demonstrated that obese individuals with OSA have larger soft tissue structures compared with normal individuals, and BMI has been shown to correlate with the percentage of fat deposition within the tongue.[54,163] In mice, tongue fat has been shown to be a heritable trait.[164] Unlike other fat distributions, the magnitude of heritability was minimally affected when controlling for differences in body weight,[164] suggesting that there are specific genetic variants that determine tongue fat, as has been shown for pericardial fat.[165] The important role of tongue fat has been further demonstrated by studies before and after weight loss.[166] As expected, OSA severity improved with weight loss (i.e., there was a fall in AHI). Data analysis revealed that the relationship between the reductions in BMI and AHI was mediated by changes in tongue fat. Thus, tongue fat is likely to be a critical link between obesity and OSA. As noted earlier, the larger size of the tongue and other soft tissue structures may promote pharyngeal collapse during sleep by increasing tissue pressure on the pharyngeal wall.[55,57,167] In addition to biomechanical effects associated with a larger tongue, obesity is also likely to have important interactions with other risk factors, such as craniofacial characteristics.

Evidence continues to accrue that leptin, a hormone produced by adipocyte tissue that plays a major role in regulating appetite and metabolism and acts as a potent ventilatory stimulant on central respiratory control nuclei,[168] also plays an important role in the pathogenesis of OSA. In obese individuals, circulating levels of leptin are markedly elevated, but the usual stimulatory effects of leptin on respiratory drive are attenuated due to leptin resistance. Leptin is also implicated in the pathogenesis of OSA through impaired central regulation of upper airway patency and diaphragmatic control.[168] In murine models, leptin deficiency and leptin resistance are associated with a higher occurrence of flow-limited breathing and pharyngeal collapsibility.[169,170] In humans, increased leptin levels have been associated with OSA severity, independent of confounders including BMI and waist circumference.[171] Leptin-mediated increases in the production of reactive oxidative species and oxidative stress may help to explain the relationship between OSA and an increased risk of cardiovascular morbidity and mortality.[168]

Physiologic Risk Factors

Nonanatomic phenotypic traits such as a low respiratory arousal threshold, an oversensitive ventilatory control system (i.e., high loop gain, a measure of ventilatory control instability), and poor pharyngeal dilator muscle effectiveness or responsiveness during sleep also appear to be particularly important in determining whether individuals with less collapsible airways manifest OSA.[172] These physiologic factors have been identified as important contributors to the development of OSA in at least one-third of patients.[172,173]

The respiratory arousal threshold describes the level of ventilatory drive needed to trigger an arousal from sleep. Individuals with lower arousal thresholds awaken due to small changes in ventilatory drive, before the pharyngeal reflexes that activate the dilator muscles of the upper airway and thus promote stable breathing, are engaged.[94] In contrast, individuals with higher respiratory arousals thresholds may be better able to engage the pharyngeal reflexes, averting obstructive apneas.

The concept of loop gain is derived from the engineering literature and is used to characterize the stability of the negative feedback loop that controls breathing.[174] More stable systems are characterized by low loop gain, in which a smaller change in ventilation occurs in response to an apnea or hypopnea. In contrast, high–loop gain systems react to an apnea or hypopnea with a larger ventilatory change and are thus more likely to become unstable due to small disturbances.

Finally, a limited ability to activate the pharyngeal dilator muscles during sleep in response to increases in ventilatory drive, that is, poor upper airway muscle responsiveness or effectiveness, appears to promote the development of sleep apnea in a subset of patients with OSA. These physiologic factors can vary widely among patients who appear to have similar degrees of OSA when assessed using the AHI. Importantly, they may be helpful in identifying patients who are likely to benefit from targeted non-CPAP interventions such as upper airway surgery,[175] supplemental oxygen,[176] and a drug stimulating upper airway muscles.[177]

Genetic Factors

Evidence that heritable risk factors for sleep apnea exist continues to accumulate. A number of studies initially demonstrated the tendency for OSA to aggregate in families.[178,179] Subsequently, studies utilizing genetic epidemiology techniques have demonstrated increased risk for OSA, independent of obesity, among first-degree relatives in geographically diverse populations in Iceland, Israel, Scotland, and Cleveland (United States).[64,180–182] The risk for OSA increases by 30% to 58% among individuals who have one first-degree relative with OSA and two- to fourfold for those with three affected family members with OSA.[134] The heritability of both soft tissue and craniofacial structures has been recognized.[67] However, while associations between promising genetic polymorphisms and OSA have been identified in numerous candidate gene studies,[183] many of these studies had inadequate sample sizes and few results have been independently replicated.[184] In a meta-analysis of three of the available studies, the *TNF*-α (*−308G/A*) polymorphism nearly doubled the odds for OSA.[185]

In recent years, genome-wide association studies have searched for relationships between genetic polymorphisms and SDB characteristics derived from PSG. Different genetic variants associated with AHI have been identified among individuals of Caribbean descent[186] and in a larger multiethnic study combining data from seven cohort studies.[187] Two studies have identified genetic variants associated with oxygen saturations during sleep and have replicated their findings.[188,189] A genome-wide study that employed whole-genome sequencing also found several rare genetic variants associated with oxygen desaturations.[189] Finally, an analytic technique known as admixture mapping that takes advantage of migration away from relatively isolated continents has likewise identified some genetic polymorphisms associated with AHI and oximetry measurements.[190]

Genome-wide analytic techniques for identifying relevant genes are continuing to evolve. Ultimately, given the complexity of SDB, many different genes are likely to contribute.

Craniofacial Anatomy

A proportion of patients with OSA are not obese. In nonobese individuals, craniofacial features such as retroposed mandible, micrognathia, and narrowing of the hard palate are the primary risk factors for apnea.[64–66] Furthermore, heritability of craniofacial abnormalities (retroposed mandible, inferior displaced hyoid bone) and upper airway soft tissue structures (tongue volume, lateral pharyngeal walls, and total soft tissue) has been demonstrated in first-degree relatives and siblings.[64,191,192] These factors may operate in concert or alone to increase the risk of apnea. Genetic disorders associated with craniofacial and/or upper airway soft tissue abnormalities, including Treacher Collins syndrome, Down syndrome, Apert syndrome, and Pierre Robin syndrome, also confer increased risk of SDB.[193]

Endocrine Abnormalities

Individuals with specific endocrine conditions are at risk for OSA. Hypothyroidism, especially when accompanied by myxedema, is associated with both OSA and CSA due to alterations in muscle function and blunted ventilatory response.[194,195] The presence of a goiter may place the patient at risk for OSA,[196] and thyroid surgery (lobectomy or total thyroidectomy) can improve OSA symptoms including snoring and excessive somnolence.[197] Macroglossia associated with hypothyroidism also contributes to the development of OSA. OSA is common and often severe in patients with acromegaly, presumably related to both osseous and soft tissue changes narrowing the upper airway.[198]

Given the low prevalence of OSA among premenopausal women compared with postmenopausal women and men, the female reproductive hormones appear to have a protective effect on OSA risk.[199–201] Interestingly, among women with polycystic ovarian syndrome, which is characterized by hyperandrogenism, obesity, and cardiometabolic dysfunction, OSA risk is markedly higher compared with age- and/or weight-matched controls.[202,203] OSA risk among postmenopausal users of hormone replacement therapy was observed in two large cohort studies to be similar to that of premenopausal women and lower compared with nonhormone users.[25,138] However, widespread cessation of hormone therapy use occurred after the July 2002 publication of results from the Women's Health Initiative study showing increased risks for cardiovascular disease and breast cancer among women taking replacement hormones.[204] Subsequent analyses of data from the Sleep in Midlife Women Study demonstrated that the protective effect of hormone therapy against sleep-disordered breathing disappeared after the release of the WHI results, suggesting that healthy user bias was the likely reason for lower SDB rates among hormone therapy users.[205]

Other Considerations

Alcohol, which reduces upper airway tone, and sedatives or hypnotics, which reduce the arousal mechanism, also can worsen OSA.[206,207] Each potential risk factor should be considered in the patient evaluation, as it is important to address why an individual has developed sleep apnea.

Recently, a large (>81,000) international sample of individuals with and without sleep apnea was examined to identify characteristics associated with "extreme phenotypes"—that is, conferring either predisposition toward or protection against OSA in those whose disease status was not explained by known risk factors.[208] Comparisons suggested that a greater cervicomental angle increases risk for OSA in the absence of other clinical risk factors, and smaller facial widths are protective when clinical risk factors are present. More broadly, identifying extreme phenotypes may help to accelerate research into unique clinical and genetic contributors to OSA.

CLINICAL PRESENTATION AND SCREENING FOR OSA

Elements in the history and physical examination, as well as screening tools useful in establishing a diagnosis of OSA, are discussed below.

■ Clinical Presentation

Below are considered important clinical aspects of OSA, including its many heterogeneous features.

History

The diagnosis of OSA is frequently suggested by the history. Patients with sleep apnea often complain of both daytime and nighttime symptoms (Table 98-2). Bed partners are crucial informants of nocturnal events, and when available, a detailed history from the bed partner is imperative in cases of suspected OSA. Snoring is the cardinal complaint reported by the bed partner. Typically, the snoring is loud and nightly and has existed for many years. Snoring may be so disruptive that the bed partner can be driven to sleep in another room.[209] A bed partner may report a witnessed apnea that is followed by a loud snort or gasp at the end of the apneic episode. This can be extremely concerning to the partner and serve as the trigger for seeking medical attention.

TABLE 98-2 Clinical Presentation of Obstructive Sleep Apnea

Loud, habitual snoring
Witnessed apneas
Nocturnal awakening
Gasping or choking episodes during sleep
Nocturia
Nocturnal sweating
Unrefreshing sleep, morning headaches
Excessive daytime sleepiness
Automobile or work-related accidents
Irritability, memory loss, personality change
Decreased libido
Impotence

Individuals with OSA may also report snorting or gasping, choking, nocturnal diaphoresis, and restlessness related to airway obstruction.[210,211] A sensation of choking or dyspnea is reported in up to 30% of patients. Frequent nocturnal awakenings related to repetitive airway obstruction lead to sleep fragmentation. Nocturia is fairly common and has been attributed to ANP release in response to apnea-related right atrial stretch.[100] A large community-based epidemiologic study found a dose–response relationship between the severity of sleep apnea and levels of brain natriuretic peptide (BNP).[212] This relationship was not observed in a similar analysis performed in a subset of participants from the Sleep Heart Health Study,[213] who were older (median age 65) and not obese. However, nocturia has been observed to improve in patients with OSA who are adherent to CPAP therapy.[214,215]

Repetitive apneic events are not conducive to restorative sleep. Some studies have shown that untreated OSA patients have decreased slow wave sleep (non-REM stage 3) and REM sleep and more sleep stage transitions.[216,217] Thus, individuals with OSA are frequently unrefreshed upon awakening in the morning. Morning headaches are a less common manifestation of sleep apnea. When reported, the possibility of hypercapnia due to OHS should be considered.[218]

Excessive daytime sleepiness is a chief clinical consequence among patients with OSA.[219] Less commonly, patients may report insomnia, with difficulties initiating and maintaining sleep.[220,221] Interestingly, although the proportion of individuals who endorse daytime sleepiness increases with OSA severity, disease severity has proven to correlate only modestly with the degree of excessive somnolence.[222,223] Typically, the excessive daytime sleepiness of individuals with OSA occurs in sedentary situations, for example, following meals, watching television, reading, and during conversation. Driving is particularly problematic in patients with sleep apnea.[224,225] Patients may report falling asleep at red lights or stop signs, drowsiness while driving, and in extreme cases, motor vehicle accidents.[226] Thus, it is imperative to inquire about drowsy driving,

TABLE 98-3 Epworth Sleepiness Scale

In contrast to just feeling tired, how likely are you to doze off or fall asleep in the following situations? (This refers to your usual life in recent times. Even if you have not done some of these things recently, try to work out how they would have affected you.) Use the following scale to choose the most appropriate number for each situation:

0 = Would never doze
1 = Slight chance of dozing
2 = Moderate chance of dozing
3 = High chance of dozing

Situation	Chance of Dozing
Sitting and reading	____________
Watching TV	____________
Sitting inactive in a public place (i.e., a theater or a meeting)	____________
As a passenger in a car for an hour without break	____________
Lying down to rest in the afternoon when circumstances permit	____________
Sitting and talking to someone	____________
Sitting quietly after lunch without alcohol	____________
In a car, while stopping for a few minutes in traffic	____________

Reproduced with permission from Johns MW. A new method for measuring daytime sleepiness: the Epworth sleepiness scale. Sleep. 1991;14(6):540–545.

which is risky not only to the patient but also to others on the road. The Epworth Sleepiness Scale (Table 98-3), a questionnaire for assessing the degree of subjective sleepiness, is usually elevated in sleep apnea patients (scored 0–24, with >10 considered abnormal) and can be a useful tool for assessing sleepiness in clinical settings.[222] Nevertheless, it is important to appreciate that the presence of excessive daytime somnolence is neither a necessary nor a sufficient condition for making the diagnosis of OSA: Many individuals with an elevated AHI do not report daytime sleepiness, and others report sleepiness in the absence of sleep apnea (often due to insufficient sleep). Whether patients with an elevated AHI who are relatively asymptomatic should be treated continues to be debated, with recent data showing that the cardiovascular benefits of treatment likely largely accrue to symptomatic patients.[227]

OSA can also cause symptoms related to cognitive impairment.[228–231] Inattention and deficits in memory and concentration often affect the ability to function at work. Fear of falling asleep inappropriately may limit an individual's willingness to integrate socially.[232] Moreover, patients with sleep apnea and/or their spouses can report irritability, depressive symptoms, and personality change.[233,234] Sexual dysfunction, that is, either decreased libido or impotence, is another common complaint among men with OSA.[235]

OSA Is a Heterogeneous Disorder

Growing evidence that OSA is a heterogeneous disorder supports the concept that a personalized approach to diagnosis and management of OSA is required.[236,237] OSA is heterogeneous from multiple points of view. The most studied aspect is differences in symptoms. This was originally identified using data from the Icelandic Sleep Apnea Cohort.[238] Based on cluster analysis of responses to extensive questionnaires, three subtypes of OSA were recognized. These included a disturbed sleep group in which individuals' main complaints were symptoms of insomnia, that is, difficulty initiating and maintaining sleep. Patients of this type were not excessively sleepy and had a normal Epworth Sleepiness Score. A second group was minimally symptomatic. This group of patients had a normal Epworth Sleepiness Score, and the vast majority reported waking up feeling refreshed. The last was an excessively sleep group. While they are what we typically envisage sleep apnea patients to be, they comprised only 42.6% of the total clinical cohort. These individuals were very sleepy with mean Epworth Sleepiness Scores of 15.7, and they frequently fell asleep driving.[238] These groups did not differ by severity of OSA (i.e., AHI), BMI, age, or gender.

These symptom subtypes have now been replicated in multiple studies, both in population-based cohorts—the Sleep Heart Health Study,[131] the Korean Genomic Cohort,[239] and the Hispanic Cohort in the United States,[240] and in clinical cohorts of patients in sleep centers—the Sleep Apnea Global Interdisciplinary Consortium (SAGIC),[241] the Canadian National Network for Sleep and Circadian Disorders,[242] and a single center cohort in Chile[243] and France.[244] In these studies, the optimal number of clusters varied between three and five, but the subtypes originally identified in Iceland were always present.

Not surprisingly, the benefit of CPAP treatment for OSA on symptoms varies between subtypes.[245] The magnitude of change in symptoms is greatest in the excessively sleepy group but quite minimal in the relatively asymptomatic group.[245]

These subtypes have different risk of other outcomes, in particular, incident cardiovascular disease. This was originally demonstrated in a study using data from the Sleep Heart Health Study, where only the excessively sleepy subgroup had an increased risk of CV events compared to controls without OSA.[131] That the excessively sleepy group has an increased risk of CV events was confirmed in the clinical cohort in Chile,[243] but not in France.[244]

Even before the formal identification of clinical subtypes, there were studies that indicated that cardiovascular risk was greater among individuals who complained of excessive sleepiness. In the Sleep Heart Health Study, an association between OSA and hypertension was observed in those who complained of sleepiness but not in those without sleepiness.[246] Patients who were found to have OSA after a myocardial infarction had higher rates of reinfarction if they were excessively sleepy compared to those with OSA who were not sleepy.[247] This increased risk of CV events is not the result of sleepiness per se since those without OSA who are excessively sleepy do not have an increased risk of cardiovascular events.[131] Rather, it is likely that different individuals respond to OSA in dissimilar ways at a molecular level. These different responses likely lead to both excessive sleepiness and cardiovascular consequences.

The role of sleepiness in OSA is an area of considerable importance since, for ethical reasons, excessively sleepy individuals have been deliberately excluded from recent randomized control studies (RCTs) examining the impact of CPAP on future cardiovascular events. Epidemiologic studies have shown that individuals with severe OSA have an increased risk of CV events over time that is nullified if they use CPAP.[248] In contrast, recent RCTs have shown no benefit of CPAP on the rate of CV events.[249–251] It has been argued that this negative result is largely the result of exclusion of subjects with excessive sleepiness coupled with low CPAP adherence in nonsleepy subjects.[227]

OSA is also heterogeneous from a physiologic point of view. Wellman et al. have argued that there are four different physiologic risk factors for OSA.[172] The magnitude of these different risk factors varies between subjects. The four physiologic risk factors are (1) collapsibility of the upper airway; (2) overall loop gain, a measure of the instability of the ventilatory control system; (3) arousal threshold; and (4) the responsiveness of the negative pressure reflex in the upper airway that augments activity of upper airway dilator muscles.[172] Early studies to support this concept required complex protocols that included measurement of EMG activity of an upper airway dilator muscle and intraluminal pressure.[172] Recently it has been asserted that information on these four variables can be obtained from a routine sleep study based on a simple model of ventilatory control.[252,253] A cloud-based software system has been developed for clinicians to obtain these data from routine sleep study recordings.[254] This approach has been challenged since it has been argued that the model is too simple and is based on untenable assumptions.[255] Currently, data are limited regarding the reliability of the measures obtained for this simple model—for example, are the same data obtained using repeat nights of testing? Moreover, there are limited validation studies comparing results obtained with gold standard measures. Thus, this is an interesting concept, but much remains to be done before it becomes widely used in clinical sleep medicine.

There are other physiologic differences in OSA. Using cluster analysis to examine standard metrics obtained from overnight PSGs, Zinchuk et al. showed that there are different physiologic subtypes.[256] Only two of the subtypes so identified had an increased risk of CV events that was reduced with CPAP treatment. This interesting result has not, to date, been replicated in other cohorts.

There are now new metrics being obtained from sleep studies.[257,258] It is argued that the AHI is not particularly predictive of outcomes, and we need to move beyond the AHI.[258] New measures include the following: intensity of arousal on a scale of 1 to 9[259]; odds ratio product (ORP), a continuous measure of sleep depth[260]; ORP9, that is, depth of sleep 9 s after an arousal, a measure of sleep drive[261]; heart rate response to an arousal[262]; and hypoxic burden across the total sleep study.[21] Both heart rate response to arousal[107] (likely a measure of sympathetic response) and hypoxic burden[21] have been shown to be predictive of mortality from CV causes. Thus, in the future we are likely to see an increasing focus on new metrics that provide better prediction of outcomes.

Physical Examination

The examination of the patient with suspected OSAS should focus on careful inspection of the head and neck, determination of the presence of obesity (BMI >30 kg/m^2), and measurement of BP. Neck circumference greater than 17 in (43.2 cm) in men or 16 in (40.6 cm) in women indicates an increased risk for OSA.[263] The evaluation should also include assessment for abnormalities of the shape and size of the craniofacial structures (e.g., mandibular retrognathia, micrognathia, crossbite, narrowing of the hard palate, and dental malocclusion); evaluation for factors contributing to nasal obstruction including nasal asymmetry, polyps, septal deviation, and hypertrophy of the turbinates; and visualization of the pharynx to assess crowding and soft tissue dimensions (macroglossia, tonsillar hypertrophy, lateral peritonsillar wall narrowing, enlarged/elongated uvula, or a narrow, high-arched hard palate). The modified Mallampati classification is often used to describe the patency of the upper airway, with increased risk for sleep apnea observed among individuals with class III or IV airways.[264]

■ Screening for Sleep Apnea

Inexpensive tools have been developed to assess the likelihood of apnea. The ability of a number of standardized instruments, such as the Multivariable Apnea Prediction (MAP) Index and the Berlin questionnaire, to identify individuals at risk for sleep apnea has been evaluated.[210,265] The sensitivity and specificity of these questionnaires tend to vary depending on the population studied, the specific cutoffs chosen, and the severity of OSA to be identified.[266] In recent years, a straightforward eight-item questionnaire (STOP-BANG) with four self-reportable criteria (STOP: Snoring, Tiredness, Observed apnea, and high blood Pressure) and four demographic items (BANG: BMI, Age, Neck circumference, and Gender) developed for the surgical preoperative setting has been shown to have good predictive value for identifying severe OSA in surgical and sleep clinic settings worldwide, and to a lesser extent in the general population and commercial driver population.[267,268] However, by dichotomizing each variable, the STOP-BANG loses the continuous nature of the variables used, such as BMI. Other clinical situations in which sleep apnea should be considered in evaluating patients are outlined in Table 98-4.

TABLE 98-4 Conditions in Which Evaluation for Obstructive Sleep Apnea Should Be Considered

Obesity
Systemic hypertension
Myocardial infarction
Cerebrovascular accident
Type 2 diabetes mellitus
Pulmonary hypertension
Polycystic ovarian syndrome
Atrial fibrillation
Driver involved in a sleep-related automobile crash
Preoperative anesthesia evaluation

In the past, overnight pulse oximetry (Fig. 98-8) has been used to screen for OSA.[269,270] Typically, patients with OSA manifest a saw-tooth pattern on nocturnal oximetry. However, overnight oximetry does not detect apneas or hypopneas or arousals in the absence of significant oxygen desaturation, rendering the sensitivity of the test suboptimal. Furthermore, abnormal ambulatory overnight oximetry results obtained by general internists based on their initial clinical suspicion for OSA frequently fail to lead to further sleep evaluation.[271]

In recent years, the digital health revolution has produced a boom in wearable technologies, including a large consumer sleep technology family of products such as smartwatches, rings, sensor clips, wristbands, armbands, and headbands. These wearables collect data on a variety of biosignals ranging from motion to heart rate, skin conductance, and temperature; an increasing number can collect and store continuous oximetry data.[272] Thus, many of these devices can infer information about sleep and sleep-disordered breathing. There is growing recognition within the clinical and research sleep communities of the potential offered by wearable sleep trackers for advancing sleep health. Likewise, the wide availability of wearable sleep technologies can promote increased interest in and awareness of sleep health in the general population. Nevertheless, data on the validity, accuracy, and reliability of wearable sleep devices for use in screening for sleep disorders and sleep-disordered breathing are relatively sparse.[272]

DIAGNOSIS OF OBSTRUCTIVE SLEEP APNEA

While questionnaires and prediction models (i.e., Epworth Sleepiness Scale, MAP) can assist in OSA risk stratification, objective sleep testing is required to confirm the diagnosis and determine disease severity.[27] Polysomnography (PSG), still the gold standard sleep study,[273] records many parameters while the patient sleeps: electroencephalogram (EEG) to indicate sleep state, electrooculogram (EOG) to monitor eye movements, electromyogram (EMG) to measure muscle activity, oronasal thermistor and nasal pressure sensors to indicate respiratory airflow, and chest and waist bands to measure respiratory effort and arterial oxygen saturation (Fig. 98-9)

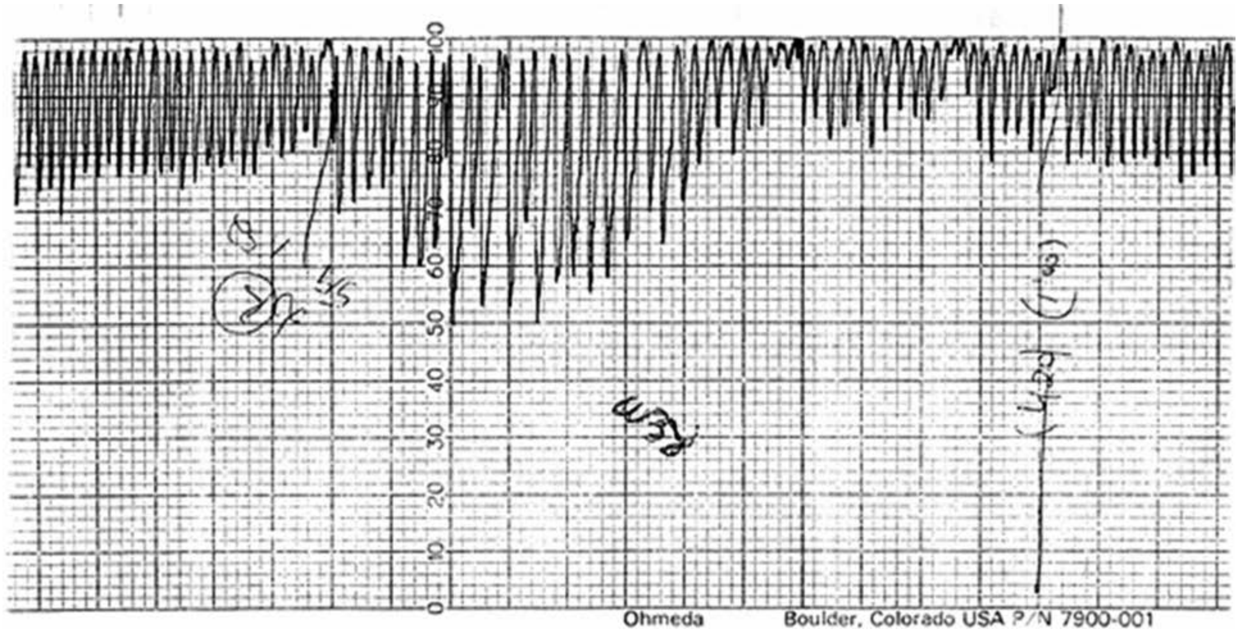

Figure 98-8 Nocturnal oximetry pattern in a patient with obstructive sleep apnea. This patient manifests recurrent oxyhemoglobin desaturations ("sawtooth pattern") that are most severe in REM sleep. Oximetry calibrated from 0% to 100%. Paper speed: each small line 1 min; each dark black line 5 min.

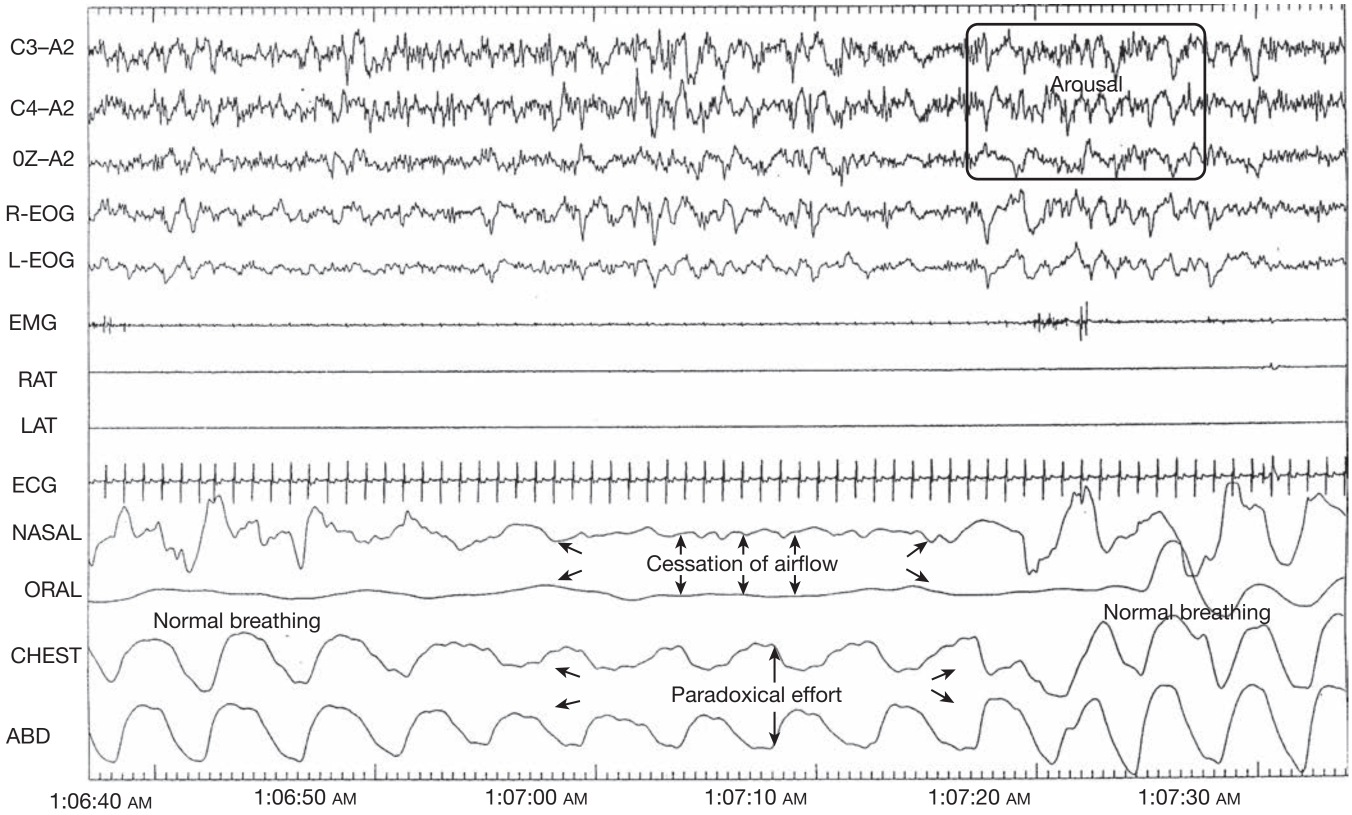

Figure 98-9 Example of an obstructive apnea in a patient with sleep apnea syndrome in stage 2 sleep. The polysomnography traces from the top down are as follows: three EEG channels *(C3–A2, C4–A2, OZ–A2)*; two EOG channels *(R and L)*; submental electromyogram *(EMG)*; right and left anterior tibialis EMG *(RAT, LAT)*, electrocardiogram *(ECG)*; nasal and oral airflow; chest and abdominal motion *(CHEST and ABD)*. During the apneic episodes, there is abnormal airflow (both oral and nasal) with paradoxical motion of the rib cage and abdomen. At the end of the apneic episode there is a burst of EMG activity at the arousal. Following the arousal, respiration resumes with synchronous movements of the rib cage and abdomen.

(Video 98-1). These measurements are integrated to provide sleep staging and to indicate apneas, hypopneas, and arousals as depicted in Figs. 98-10 and 98-11.

PSG data have been used to generate the most common measure of sleep apnea severity—the AHI—for several decades. However, new analyses of the data obtained have produced new metrics that better characterize clinical impacts and mortality risk from sleep-disordered breathing. For instance, the AHI can fail to identify patients who obtain most cardiovascular benefit from OSA treatment.[258] As noted in the “Sleep Apnea Definitions” section, Azarbarzin et al. showed the hypoxic burden correlates better with cardiovascular disease mortality than the AHI.[21] The metric is easy to calculate from conventional PSG data. Other potentially useful alternatives to AHI include arousal intensity, odds ratio product (quantifying sleep depth), cardiopulmonary coupling, and apnea–hypopnea event duration.[258]

Stratifying disease severity through the AHI is important, given demonstrated linearity between increasing AHI and likelihood of adverse outcomes (e.g., hypertension, cardiovascular mortality, stroke).[248,274,275] However, despite the ubiquitous use of AHI in OSA diagnosis, the index has some limitations. First, AHI elevations often fail to correlate with sleep quality measures and clinical outcomes.[276] In addition, AHI does not capture other significant aspects of the disorder, such as the degree of oxyhemoglobin desaturation, nocturnal hypoxemia, hypoventilation (i.e., hypercapnia), or associated sleep disruption. Furthermore, variance in hypopnea definitions has led to substantial disparities in measured severity of SDB.[15,17] Despite these shortcomings, the AHI remains the primary determinant of OSA diagnosis and severity.[27] Other metrics have been suggested to better characterize disease impact and severity, and other strategies (symptom subtypes, genetics, blood biomarkers, machine learning, wearable technologies) are being developed.[258]

While in-laboratory PSG remains the gold standard to establish AHI, limited patient access and relatively high cost have led to increasing use of out-of-center sleep testing—also known as portable monitoring, unattended sleep testing, or home sleep apnea testing (HSAT) (Video 98-2). Kuna et al.[277] have established the value of HSAT in terms of patient outcomes and treatment adherence. The researchers randomized veterans to undergo sleep apnea testing either through PSG or HSAT. Patients diagnosed with OSA either were brought back to the laboratory for PAP titration (PSG arm) or underwent home auto-PAP titration (HSAT arm). After 3 months of treatment, neither functional outcome improvement nor PAP adherence was clinically inferior in the HSAT study arm compared with the PSG study arm.

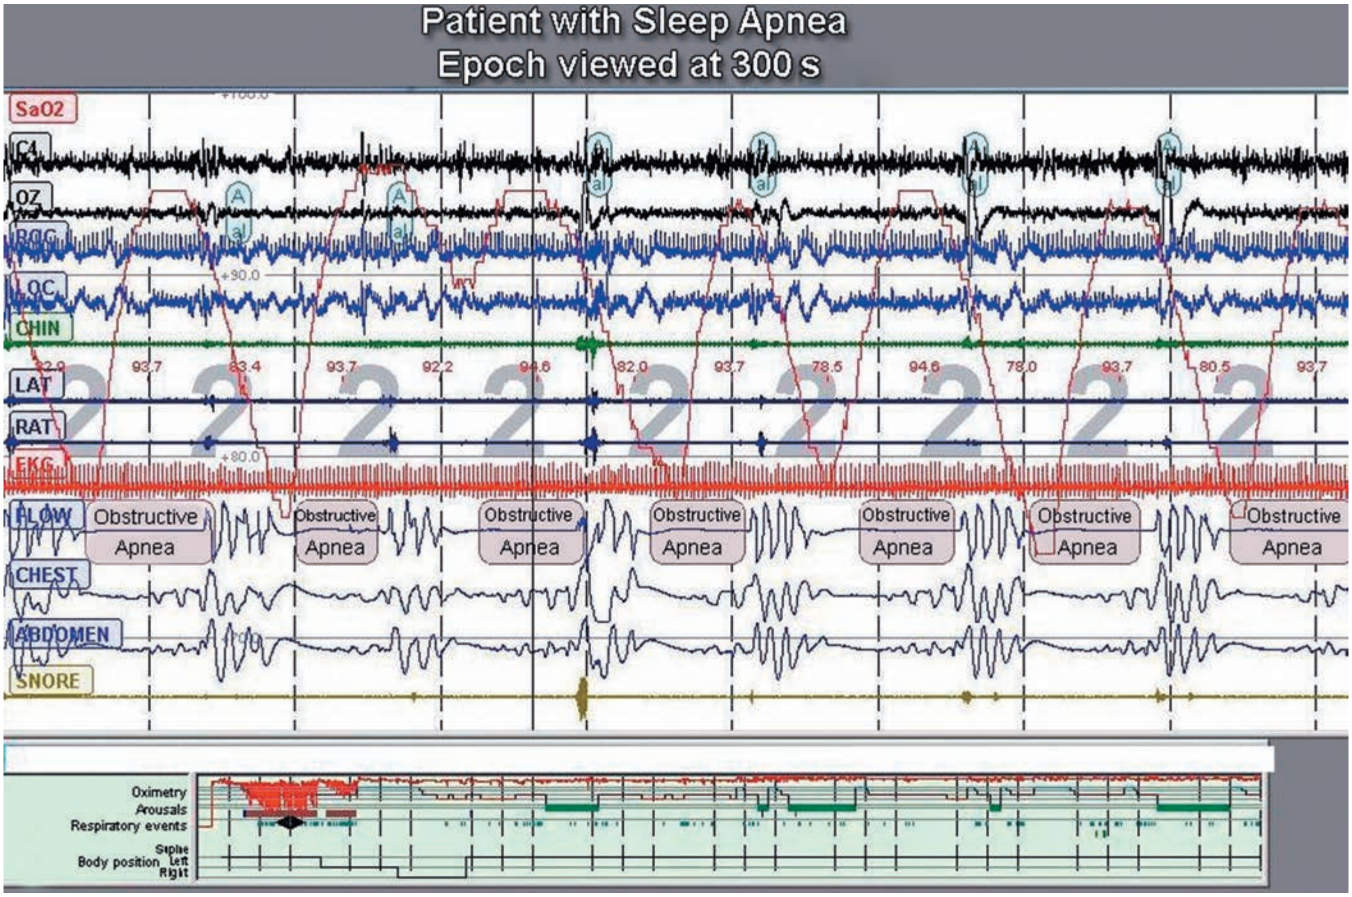

Figure 98-10 Example of a sleep study epoch from a split night sleep study in a patient with severe apnea. The epoch is viewed at 300 s. This patient has recurrent apneic events associated with oxyhemoglobin desaturations *(recurrent dips in the red line)*. At the bottom of the figure is a hypnogram displaying the sleep data from the entire night. The *black diamond* in the hypnogram shows the time frame for the specific epoch displayed in the top portion of the figure. Later on in the night the patient is started on CPAP and the recurrent apneas and oxyhemoglobin desaturations are abolished (the recurrent desaturations: *red lines* noted in the hypnogram resolve). *C4* and *OZ* are EEG leads; *ROC* and *LOC* are the right and left ocular leads; *RAT* and *LAT* are the right and left anterior tibialis electromyograms; Sa_{O_2} is the oximetry lead.

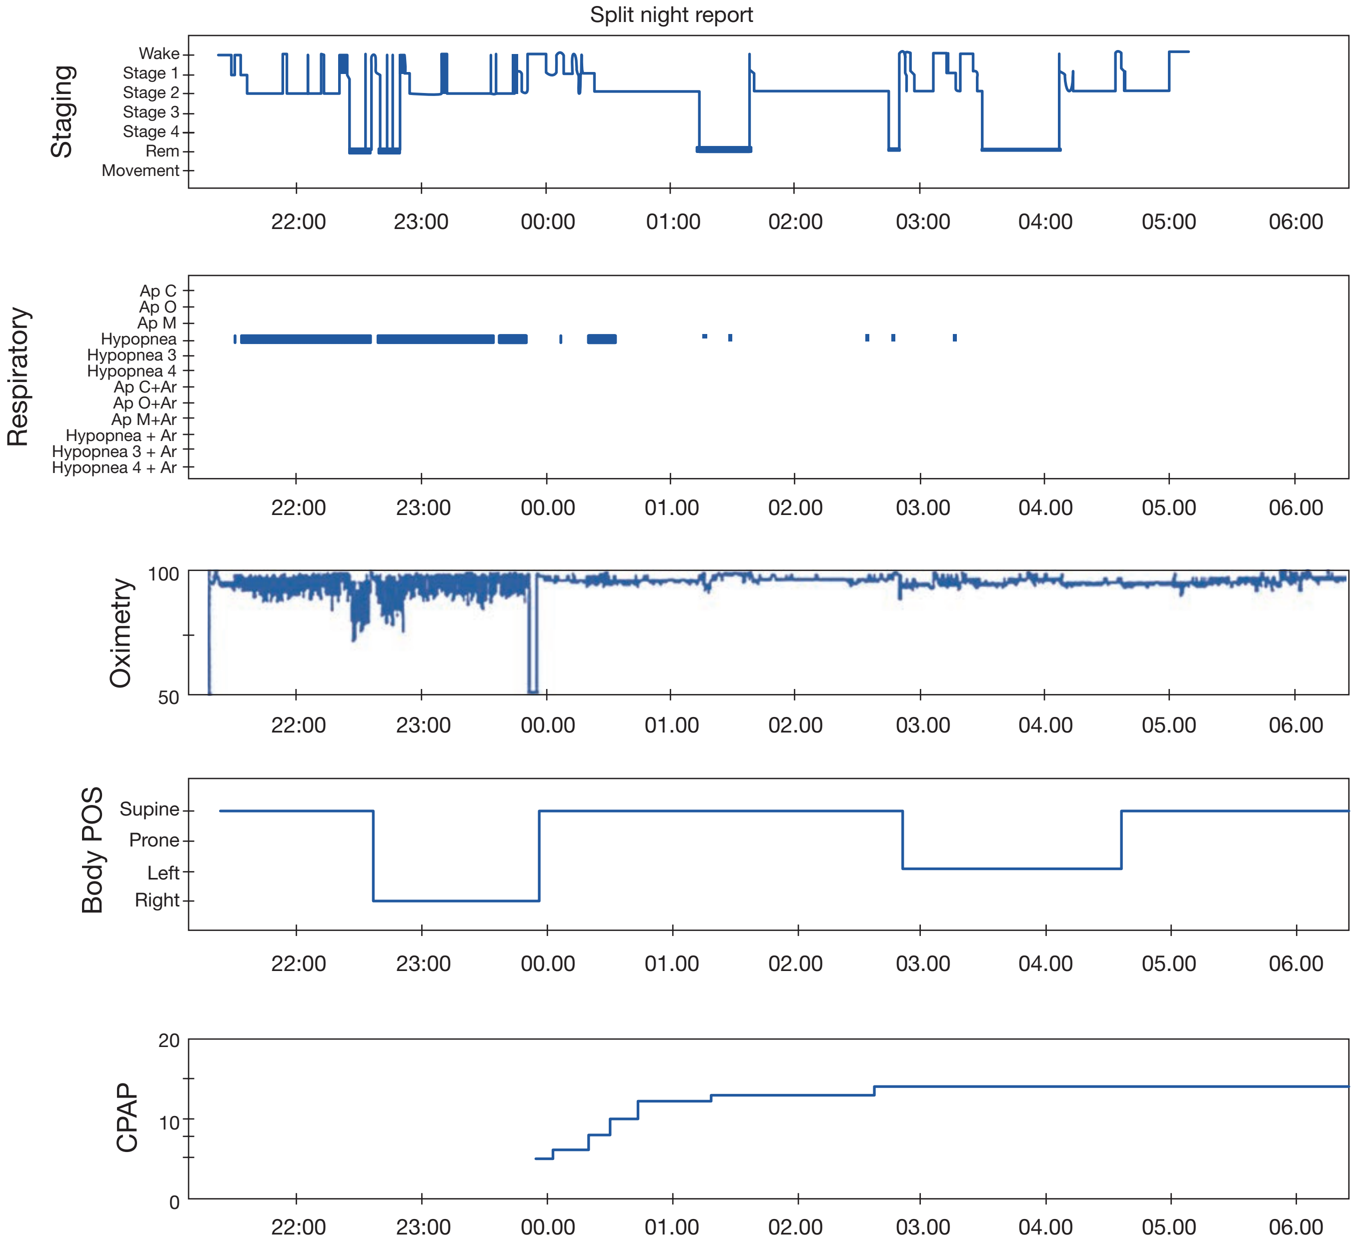

Figure 98-11 Split night hypnogram in a patient with obstructive sleep apnea. The patient has frequent hypopneas with recurrent oxyhemoglobin desaturations until he is started on CPAP at midnight. The CPAP was titrated to 14 cm H_2O, which abolished the hypopneas and oxyhemoglobin desaturations.

Typically performed in patients' homes, HSAT offers greater convenience at lower cost, and ideally replicates a usual night of sleep. The amount of data procured ranges widely, depending on the AASM-designated type of sleep testing performed (Table 98-5). An in-laboratory PSG as described earlier is designated a type I study. Overall, type II and III studies are differentiated by the number of variables measured. The former is a complete unattended home study and measures the same parameters as a type I study (PSG). Type II studies are rarely performed in clinical practice, although new devices now allow for sleep staging using strategies such as odds ratio product and delta spectral power calculations.[278] Type III studies typically include measurement of airflow, respiratory effort, pulse, and sleep position. Since EEG is not obtained, sleep stage information and stage-related events (e.g., arousals) cannot be detected. Type IV studies are limited to only one or two parameters, such as pulse rate and oximetry. The United States Centers for Medicare and Medicaid Services outlined guidelines for use of portable sleep testing for OSA diagnosis and treatment initiation in 2009.[26]

Emerging HSAT technology has challenged this type I–IV classification. For instance, some devices utilize peripheral arterial tonometry (PAT) along with oxygen desaturation and pulse rate in their diagnostic algorithms to characterize SDB events. These devices do *not* utilize direct measurements of airflow traditionally observed in type III devices (and PSGs) and have been validated against PSG to diagnose OSA.[279] An alternative HSAT categorization system, the SCOPER classification[280] takes into account Sleep, Cardiovascular, Oximetry, Position, Effort and Respiratory parameters in categorizing emerging devices. SCOPER denotation for PAT devices might appear as $S_3C_2O_{1x}P_2E_0R_0$.

Wearable consumer technologies also are challenging the traditional HSAT classification. Multiple manufacturers now sell devices purporting to track total sleep time, sleep efficiency, and even oxygen desaturations.[281] One recent study compared 4 wearable consumer devices to actigraphy and PSG in terms of sleep/wake detection and sleep stage delineation in 34 healthy young adults. Most devices performed similarly or better than actigraphy in detecting

TABLE 98-5 Diagnostic Testing Options for Sleep-disordered Breathing

	Type	Parameters Measured
	I	EEG, EOG, EMG, ECG, airflow, respiratory effort, O_2 saturation, usually video (all conducted in a sleep laboratory with a sleep professional present)
Out-of-center testing	II	Minimum of seven channels including EEG, EOG, chin EMG, ECG/HR, airflow, respiratory effort, and O_2 saturation
	III	Minimum of four channels including ECG/HR, O_2 saturation and at least two channels of respiratory movement or respiratory movement and airflow
	IV	Airflow and/or O_2 saturation[a]

[a] Centers for Medicare and Medicaid Services require measuring a minimum of three channels, at least one of which is airflow.

EEG, electroencephalogram; EOG, electrooculogram; EMG, electromyogram; ECG, electrocardiogram; HR, heart rate.

sleep, although sleep stage delineation was frequently inaccurate.[282] While not yet approved for SDB diagnosis or treatment, these devices may be useful in their potential to enhance patient engagement and patient–provider interaction in the future.[283]

In general, portable monitors' accuracy and precision relative to PSG have been easier to question than to demonstrate. Significant differences among monitor brands of the same type, inherent night-to-night variability of AHI which is also noted on in-laboratory PSG, and difficulties keeping pace with emerging technologies have all limited research in the field. AHIs determined from type III studies tend to underestimate PSG indices largely due to absence of EEG leads; PSG AHI is calculated as the number of respiratory events per hour of *sleep*, while type III monitor AHI is based on hours of *use*. In addition, hypopneas can be underdiagnosed in the absence of EEG (as arousals used to score hypopneas cannot be reliably determined). Therefore, portable monitors may have reduced sensitivity to detect OSA, especially in patients with mild disease.[284] Nevertheless, overreliance on AHI as the gold standard of measurement of disease severity is fraught with pitfalls as described above. Thus, a key measure from HSAT may not be its agreement with PSG AHI but rather that functional outcomes were not inferior when HSAT was used, compared with PSG-based assessment.[277]

Once the diagnosis is made, treatment decisions among providers (CPAP or no CPAP) are more heterogeneous for patients with portable monitor–diagnosed mild to moderate OSA compared with patients diagnosed with mild to moderate OSA through PSG.[285] Nevertheless, functional outcomes after treatment have not differed in patients with a high pretest probability for OSA diagnosed using portable monitors, compared with in-laboratory PSG.[277,286]

Guidelines were updated for portable sleep testing in 2007[287] and for all OSA testing in 2017.[273] They recommend that out-of-center sleep testing with a portable monitor be performed only in patients with high pretest probability of moderate to severe OSA without significant comorbidities including CHF, severe COPD, and neuromuscular disease, risk of CSA, or suspicion of other sleep disorders such as parasomnias or narcolepsy. Out-of-center testing is recommended when in-laboratory PSG is not feasible due to immobility, safety, or critical illness; or in patients who need assessment of responses to non-CPAP treatment (i.e., oral appliance, upper airway surgery, weight loss). If a single HSAT is negative or technically inadequate, PSG is recommended to confirm the presence or absence of OSA.[277] Kuna et al. found that, of 35 patients with inconclusive results on their HSAT, 27 (77%) were found to have sleep apnea on their PSG.

Despite these guidelines, utilization of portable sleep monitoring varies widely due to a number of factors, including local availability of in-laboratory PSG and the burgeoning number of insurers now mandating portable testing in lieu of PSG.[288] An algorithm for appropriate testing modalities for SDB can be seen in Fig. 98-12.

In summary, in-laboratory PSG represents the gold standard for diagnosing sleep apnea. Technologic advancements in portable monitors and acceptance of out-of-center sleep testing by third-party payers has led to increased access to diagnostic testing. However, excessive focus on the significance of absolute elevations in AHI can hamper the diagnosis and treatment of OSA. Patients may exhibit similar AHI but experience different quality of sleep and outcomes. Important variables such as oxygen desaturation, number of arousals, and apnea/hypopnea length are not reflected by the AHI. Furthermore, it is not the AHI itself but the consequences (hypertension, myocardial infarction [MI], stroke, cardiac arrhythmias, excessive daytime sleepiness) of sleep apnea that are of paramount importance.

CONSEQUENCES OF OBSTRUCTIVE SLEEP APNEA

The number of recognized associations with sleep apnea has increased considerably. OSA sequelae can be broadly categorized by their neurocognitive, cardiovascular, metabolic, and neoplastic effects. OSA should be seen as a systemic disorder with effects on multiple organ systems since all tissues are subjected to CIH, although this effect varies between tissues.[289] Figure 98-13 is a simplified representation of three principal disturbances associated with apnea during sleep, the proposed downstream pathophysiologic mechanisms, and reported clinical consequences. This is not a complete depiction of all that is known, and many factors operate in a complex interplay that can jointly augment health risk.

Neurocognitive Consequences of OSA

OSA-associated neurocognitive dysfunction may occur via a hypoxia/reperfusion injury mechanism whereby increased lipid peroxidation induces oxidative stress within neural tissue.[290,291] Neurovascular endothelial dysfunction has also been demonstrated in OSA patients, leading to an imbalance between vasodilation and vasoconstriction imbalance; lower nitric oxide levels in OSA patients appear to be a key mediator.[292] Dysregulated endothelium can also lead to hypercoagulability and atherosclerosis, potentially placing patients at higher risk of vascular dementia.[293] Indeed, OSA has also been linked to increased risk of developing vascular dementia and Alzheimer disease.[294–297] Patients with OSA have increased build-up of β-amyloid, a protein linked to the development of Alzheimer disease, compared to controls without OSA.[298] Data showing impact of PAP therapy on dementia progression are lacking, and recent research exploring its impact on mild cognitive impairment progression has been mixed.[299,300] Further research in this area is ongoing and greatly needed.

Excessive daytime sleepiness and sleep fragmentation associated with sleep apnea can lead to diminished cognitive function, affecting attention, memory, vigilance, and executive function.[301–304] While motor speed appears to be spared, fine motor coordination is impaired in OSA patients.[228,304,305] Despite these associations, data from the Apnea Positive Pressure Long-term Efficacy Study (APPLES) failed to show correlation between AHI and neurocognitive performance after adjusting for ethnicity, educational level, and gender in a cross-sectional cohort.[306] There were no significant improvements in neurocognition performance with CPAP therapy. However, this negative finding may reflect participant selection; participants had normal cognitive function and had attained a relatively high grade level of education (mean, 15.5 years) before entering the study. Modest relationships between oxygen desaturation and neurocognitive performance were observed in this study and in the Sleep Heart Health Study.[307,308] Although the APPLES study's methodology has been questioned, these studies demonstrate inherent difficulties in establishing the nature and prevalence of neurocognitive sequelae among OSA patients.[309]

There may be several reasons for such complexities. First, there are many facets of cognition that are difficult to capture with a single test or study protocol. For instance, broad domains of cognitive function include executive function, visuospatial planning, memory, attention, processing speed, and language. Therefore, "cognitive" effects of untreated OSA may manifest in one area but not another. Second, the cognition-OSA link can be affected by many individual factors, such as genetics, cerebrovascular adaptations to OSA, duration of presence of OSA, and experience of sleep and

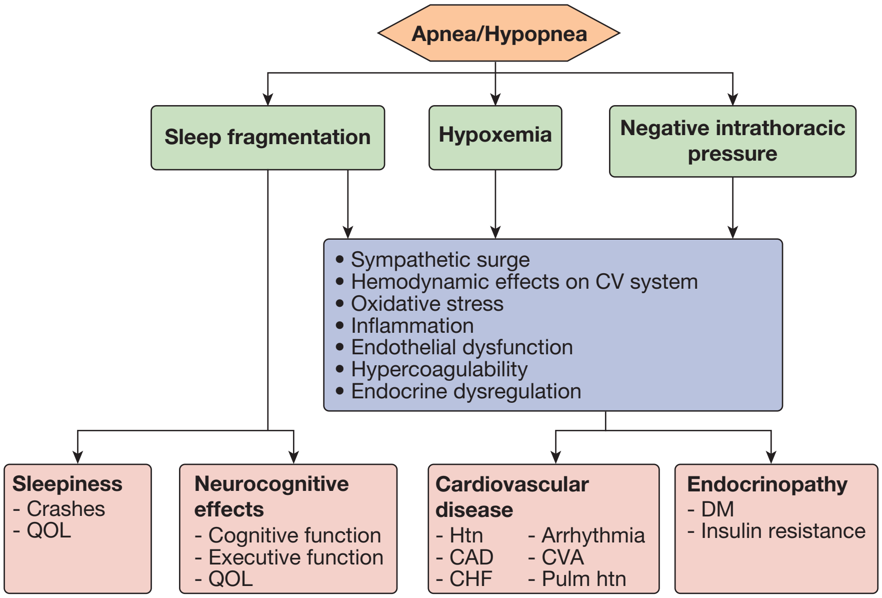

Figure 98-13 Flow chart of the proposed pathophysiologic mechanisms and consequences of obstructive sleep apnea. CHF, congestive heart failure; CV, cardiovascular; CVA, cerebrovascular accident; DM, diabetes mellitus; Htn, hypertension; Pulm htn, pulmonary hypertension; QOL, quality of life.

fatigue. Indeed, some to-be-determined patient groups may be more susceptible to cognitive effects of OSA than others. Third, studies looking at this relationship have been plagued by methodologic issues such as small sample sizes that reduce their power to find effects that may exist. Additionally, using AHI to determine OSA severity minimizes the contribution of other factors, such as arousals, respiratory event duration, and hypoxic burden, that could more closely correlate with neurocognitive impairment.[310]

OSA-related daytime sleepiness, attention lapses, and reduced vigilance are particularly salient when considering motor vehicle crashes. Several studies and a meta-analysis have shown that these patients with OSA have at least a twofold increase in relative risk of automobile accidents; up to 20% of crashes are due to sleepiness, with OSA as the most common contributing medical cause.[224,311–313] When treated with CPAP, accident rates return to those of the general population.[314] This creates an intriguing medicolegal quandary for physicians treating nonadherent OSA patients who are known to drive drowsy. Practicing physicians should understand the relevant laws in their own state for guiding decisions regarding monitoring of drivers and reporting to appropriate agencies. The American Thoracic Society has published guidelines regarding OSA and driving that support expedited diagnosis using PSG and/or out-of-center testing and rapid treatment with PAP therapy.[313] Clinicians should also consider implementation of a practice-based plan for patient education regarding drowsy driving risks and countermeasures.[313]

Special consideration should be given to commercial motor vehicle (CMV) operators with OSA given the increased risk of fatality in truck, train, and bus crashes.[315–318] Unfortunately, there is no unified regulatory mandate for OSA screening in these CMV operators.[319] The American Academy of Sleep Medicine (AASM) and Transportation Safety Awareness Task Force recommends that objective measures be used to screen all CMV operators for OSA.[320] The most common measures are body mass index (BMI), neck circumference, and the presence of hypertension; self-reported measurements of excessive sleepiness are less reliable due to their subjectivity and vulnerability to symptomatic minimization. Some major trucking companies now screen their drivers for OSA, with significant savings shown in non-OSA related medical insurance claim costs.[321–323]

Untreated OSA has also been independently associated with depression.[233] SDB should be considered in anyone suffering from this mood disorder. Beyond depressive symptoms per se, OSA also impacts quality of life as measured by the Functional Outcomes of Sleepiness Questionnaire (FOSQ) and the Sleep Apnea Quality of Life Instrument (SAQLI).[324,325] CPAP therapy has been shown to improve these measures[326] as well as more mood-specific measures such as the Hospital Anxiety and Depression scale.[327]

■ Cardiovascular Consequences of OSA

A number of cardiovascular consequences of sleep apnea have been reported. While each is discussed individually, they share common and complex pathophysiology. Obstructive apneas result in recurrent hypoxia, repetitive arousals, and large swings in intrathoracic pressure.[328] These processes lead to an array of maladaptive mechanisms: sympathetic surges, oxidative stress, inflammation, vascular endothelial dysfunction, metabolic dysregulation, hypercoagulability, and mechanical effects on the heart and vessels.[161,162,291,329–341] Each of these physiologic responses to apnea has been the focus of detailed research and requires further reading beyond the scope of this chapter. Overall, it is evident that sleep apnea induces physiologic processes conducive to the development of cardiovascular disease; results from a 10-year nonrandomized controlled observational study of patients with and without OSA showed that untreated severe OSA patients had a 2.9-fold increased rate of fatal cardiovascular events after adjusting for confounding variables (Fig. 98-14).[248]

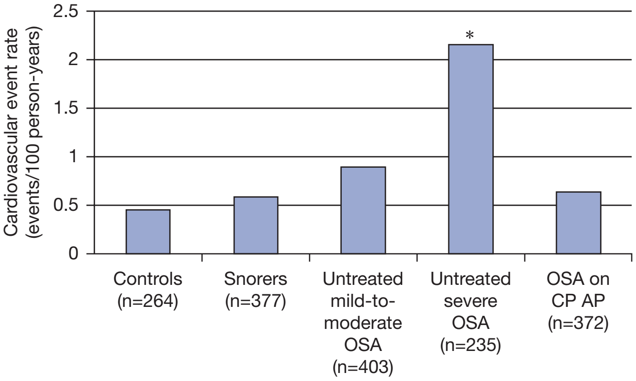

Figure 98-14 Cardiovascular event incidence during 10-year follow-up in healthy men (controls), snorers, and treated and untreated OSA patients. $^{*}p < 0.0001$ vs. healthy men. *(Data from Marin JM, Carrizo SJ, Vicente E, et al. Long-term cardiovascular outcomes in men with obstructive sleep apnoea-hypopnoea with or without treatment with continuous positive airway pressure: an observational study. Lancet. 2005;365(9464):1046–1053.)*

Hypertension

Data persuasively link OSA with systemic hypertension. About half of patients with known OSA have coexisting hypertension, and 30% to 40% of patients with hypertension have OSA.[342–344] The prevalence of OSA in patients with resistant hypertension is even higher; Logan et al.[345] studied subjects with resistant hypertension who were all taking optimal doses of at least three antihypertensive agents and found an OSA (AHI ≥10 events/h) prevalence of 83% with a mean AHI of 25 events/h.

A canine model of sleep apnea demonstrated that recurrent occlusion of a tracheostomy each time the animal fell asleep led to the development of hypertension, both acutely during the sleeping period and subsequently chronically during the wake period even though the airway was no longer occluded.[346] Implicated mechanisms behind this phenomenon in humans include alterations in output of the sympathetic nervous system and changes in the renin–angiotensin system,[39] endothelial dysfunction,[347] inflammation,[348] and metabolic dysregulation (described further below).[349]

In humans, OSA has ranked among the main causes of secondary hypertension, with several large cross-sectional studies demonstrating this relationship.[350] In the Sleep Heart Health Study, the odds ratio for the presence of hypertension in the highest category of AHI (≥30 events/h) was 1.37 compared with the lowest category AHI (<1.5 events/h) for adults younger than 65 years of age.[351] The Wisconsin Sleep Cohort Study, a prospective population-based study, demonstrated an increased risk of incident hypertension in patients with even mild OSA (AHI 5–15 events/h). Independent of BMI, the odds ratio was 2.0 for mild (AHI 5–15 events/h) and 2.9 for moderate or severe sleep apnea (AHI ≥15 events/h) over a 4- to 8-year follow-up period.[352] Among individuals in a prospective cohort of patients who were diagnosed with OSA, those patients who did not utilize therapy with CPAP had a significantly higher risk of incident hypertension compared to controls without OSA, whereas the risk for incident hypertension among OSA patients who did use CPAP was lower and similar to the control group.[353]

In several randomized trials, treatment of OSA with continuous positive airway pressure (CPAP) has been shown to reduce BP, particularly if OSA is severe. In these studies, BP was significantly lowered not only in patients with resistant hypertension, but also in patients with relatively mild hypertension. One randomized controlled trial demonstrated that several weeks to months of CPAP resulted in a significant reduction in daytime BP up to 5.1 mm Hg compared to treatment with subtherapeutic CPAP.[354] A meta-analysis of 16 randomized trials comparing CPAP users to OSA-positive nonusers found a mean net decrease in systolic pressure of 2.46 mm Hg in the former group compared with the latter.[355] This effect may appear modest, but antihypertensive literature shows a 41% decline in stroke and a 22% decline in coronary artery disease (CAD) from just a 5-mm Hg decline in diastolic BP; even a 2-mm Hg diastolic BP drop may decrease these risks by 15% and 6%, respectively.[356,357] CPAP had less effect on incident hypertension in a nonsleepy OSA population (AHI ≥20 events/h).[358]

CPAP impacts BP elevation most in patients with resistant hypertension. One study found a mean arterial pressure drop of 5.6 mm Hg in CPAP-adherent, resistant hypertension patients versus a drop of 0.8 mm Hg in CPAP-adherent patients with controlled hypertension.[359] Nearly 71% of these resistant hypertensive patients had their antihypertension regimen simplified after CPAP.[359] Other work has shown up to a 7.3-mm Hg drop in nocturnal systolic pressure in similar resistant hypertension patients using CPAP, with resumption of normal nocturnal BP dipping observed in 27% of their 33-person cohort.[360] This work was later replicated in a larger randomized trial.[361] A meta-analysis of 6 studies reveals ambulatory systolic and diastolic pressure declines consistent with these findings.[362] These beneficial effects of CPAP on hypertension, however, should not detract from emphasis on conventional pharmacologic methods of lowering BP.

Myocardial and Cerebrovascular Events

OSA has been associated with MI and stroke in cross-sectional studies, with a large longitudinal follow-up study confirming increased rates of cardiovascular events and cardiovascular mortality in patients with untreated severe OSA (Fig. 98-13).[248,363,364] One study showed increased cardiovascular event rates even in patients with moderate OSA.[365]

Specifically considering the stroke literature, OSA prevalence among these patients ranges from 50% to 70%.[366] Therefore, all stroke patients should be screened for OSA. Results from the Sleep Heart Health Study reveal that men with moderately severe OSA have an almost threefold increased risk of ischemic stroke compared to men without OSA. In fact, stroke risk in men increased 6% with every 1-unit increase in AHI between 5 and 25 events/h. The effect is not as strong in women, with risk of stroke only significantly increased at AHI >25 events/h.[275]

OSA likely leads to MI and cerebrovascular events in a variety of ways. Hypoxic events during sleep may trigger them; individuals with OSA who suffered an MI are more likely to have had their acute event between the hours of midnight and 6:00 AM than OSA-free individuals.[367] Another contributor could be OSA-related oxidative stress and proinflammatory state, leading to atherosclerosis. This has been demonstrated in a mouse model.[368] In addition, snoring is associated with plaques in the carotid arteries but not the femoral arteries, even in patients with few apneas.[369] Since rat tail vibration has been previously shown to induce blood vessel endothelial damage, snoring-related vibration may have a similar effect on the carotid arteries, increasing risk of stroke.[370] Should this concept be further demonstrated in humans, treating any patient who snores—regardless of OSA status—could become the norm.

Data demonstrating the impact of PAP therapy in this area have been conflicting. One recent meta-analysis comparing OSA patients using PAP to untreated OSA patients showed a lower rate of major adverse cardiovascular and cerebrovascular events (risk ratio, 0.46; 95% confidence interval [CI], 0.32–0.66) and all-cause mortality[371] (risk ratio, 0.40; 95% CI, 0.24–0.69). Nevertheless, two randomized trials—the Sleep Apnea Cardiovascular Endpoints (SAVE) study[249] and the Impact of Sleep Apnea Syndrome in the Evolution of Acute Coronary Syndrome (ISAACC) study[250]—failed to demonstrate similar improvements in cardio/cerebrovascular event reduction or mortality with PAP therapy.

Proposed reasons for this discrepancy include the exclusion of excessively sleepy patients and low PAP adherence in the later two trials.[372] Excluding sleepy patients leads to selection bias that may have skewed the study findings toward negative results. Sleepy adults with OSA suffer greater cardiovascular risk from the disorder than nonsleepy adults with OSA, yet this important group has been excluded from analyses; there are ethical concerns about randomizing sleepy patients to absent or “sham” PAP therapy given the increased risk of vehicle crashes.[227] Another methodologic concern about these studies is low adherence to PAP. Mean PAP use was just 3.3 h per night over the duration of the SAVE study, and median PAP use was just 2.2 h per night over the duration of the ISAACC study. Recent observational data in a clinical population revealed a median PAP adherence of 5.6 h nightly.[373] Therefore, the conclusions of these RCTS are not applicable to clinical patients who present for treatment of OSA.[374]

Other Cardiovascular Consequences of Sleep Apnea

OSA adversely impacts a number of other cardiovascular outcomes including CAD and CHF. The Sleep Heart Health Study studied men and women ≥40 years old who were free of CAD and CHF at baseline.[375] After a median 8.7-year follow-up and adjusting for multiple risk factors, they found OSA to be a significant predictor of CAD in men (but not women) ≤70 years of age. Men age 40 to 70 were 68% more likely to develop CAD if they had severe OSA than no OSA. Men were also 58% more likely to develop incident CHF when comparing these two groups. Explanations for the observed sex differences are unclear but may include less lifetime exposure to OSA in women due to their tendency to develop the disorder after menopause, and possible sex differences in physiologic response to OSA.[375]

There are several pathophysiologic explanations for higher rates of CHF in OSA patients.[376] Generation of negative intrathoracic pressure resulting from obstructive apneic events can increase the difference between extracardiac and intracardiac forces, increasing LV transmural pressure and leading to LV hypertrophy.[377] Apneic events can also distend the right ventricle, as increased filling (due to negative intrathoracic pressure) and pulmonary vasoconstriction (due to hypoxia) occur simultaneously. Leftward shifting of the intraventricular septum can occur, resulting in reduced LV filling and stroke volume.[378] OSA-associated hypoxia has also been shown to decrease systolic contractility directly while impairing diastolic relaxation.[379,380]

Cardiac arrhythmias have also been associated with OSA. Relatively benign arrhythmias (i.e., bradycardia/tachycardia [bradycardia during the apnea and tachycardia during the arousal], atrial premature contractions, and ventricular ectopy) have long been observed, but ongoing attention has focused on atrial fibrillation.[328] Data from the Sleep Heart Health Study have shown that atrial fibrillation is more common in patients with severe OSA than in those without OSA,[381] and a more recent Canadian study showed an 85% prevalence of OSA of any severity among atrial fibrillation patients.[382] In a recent randomized controlled trial of patients with moderate to severe sleep apnea and paroxysmal atrial fibrillation who were awaiting ablation, CPAP treatment did not result in a significant reduction in the percentage of time in atrial fibrillation.[383] However, as in other studies described above, patients with more significant excessive daytime sleepiness were excluded from this trial, which may have biased the results. In nonrandomized studies, patients with treated OSA who underwent cardioversion or pulmonary vein isolation have been observed to be 35% to 40% less likely to have recurrence of atrial fibrillation in the first year than patients with untreated OSA.[384] Randomized controlled trials of OSA treatment in patients after ablative therapy for atrial fibrillation are ongoing (*clinicaltrials.gov/ct2/show/NCT02727192* and *www.anzctr.org.au/Trial/Registration/TrialReview.aspx?id=369157*).

Metabolic Consequences of OSA

OSA has been proposed as an additional component of the metabolic syndrome, a multisystem disorder currently characterized by obesity, impaired fasting glucose, hypertriglyceridemia, and reduced high-density lipoprotein (HDL). In fact, OSA has been independently associated with each component of this syndrome; individuals with OSA (AHI ≥15 events/h) have about 5.9 to 9 times the likelihood of having the metabolic syndrome compared to individuals without OSA.[385–387] Specifically considering glucose tolerance, up to 86% of type 2 diabetes patients have at least mild OSA (AHI ≥5 events/h).[388] A study that followed diabetes-free men for 10 years showed that development of diabetes was independently associated with presence of OSA at baseline.[389] Similarly, recent studies show increased incidence of nonalcoholic fatty liver disease (NAFLD) among OSA patients.[390]

There is evidence of OSA as an independent risk factor for insulin resistance (controlling for obesity) in general population and sleep center cohort studies.[161,391] Results from intervention studies have been mixed, with CPAP therapy leading to improved glycemic control in one study, but having no significant impact in another.[392,393] An observational study of 1233 veterans revealed a direct relationship between increasing OSA severity and likelihood of conversion from prediabetes to diabetes, even after adjusting for age, sex, race, baseline fasting blood glucose, BMI, and weight change. PAP use attenuated the risk of incident diabetes in this population.[394] Similarly, a resistance to leptin, the satiety-signal hormone produced in adipose tissue that plays a role in glucose and fatty acid metabolism, has been observed among patients with OSA. Leptin levels increase proportionally with OSA severity, and they are recognized markers of cardiovascular risk.[349] Similarly, dyslipidemia has been associated with OSA both biochemically and clinically; oxidative stress due to intermittent hypoxia appears to be an important mediator.[395,396] Observational studies have suggested that lipid profiles improve with CPAP therapy,[397] but randomized controlled trial data suggest less of an effect.[398,399]

Mechanisms underlying the link between OSA and metabolic syndrome are likely complex and remain to be fully elucidated. Chronic intermittent hypoxia exposure and sleep fragmentation are key mediators that may trigger a systemic inflammatory response.[400] At a minimum, patients with OSA should be assessed for the presence of relevant metabolic disturbances and the metabolic syndrome. Obese patients with type 2 diabetes mellitus should be screened for OSA.

Oncologic Consequences of OSA

Intermittent hypoxia from OSA has also been implicated in the development of cancer,[401] its progression,[402] and cancer outcomes.[403] Long-term data from the Wisconsin Sleep Cohort showed cancer-related mortality rates increased directly with OSA severity, defined by AHI and degree of hypoxia during the sleep period.[404,405] Other studies have linked OSA with specific types of cancer, such as breast,[406] central nervous system cancer,[407] and lung cancer.[408] However, some studies have failed to show an OSA-cancer association. For instance, one Canadian study found no relationship between increased cancer incidence or prevalence and OSA.[409] A meta-analysis produced similar findings.[410] Hypotheses to reconcile these disparate findings include differences in observation length (longer observation times tend to favor finding an association) and measure of OSA severity utilized (stronger association with utilization of hypoxemia, rather than AHI).[403] The impact of OSA treatment on cancer incidence, prevalence, or mortality is yet to be determined.

Mortality

Several cohort studies, including the Wisconsin Sleep Cohort, Busselton Health Study, and the Sleep Heart Health Study demonstrate an association between untreated OSA and increased mortality.[274,411,412] This relationship is strongest when considering cardiovascular mortality in individuals with severe OSA.[412] A study of patients with ischemic heart disease showed a dose–response relationship between OSA severity and mortality, reinforcing the importance of OSA screening in this population.[413] Previous studies have shown that survival curves for patients with severe OSA are identical whether or not they complain of sleepiness, supporting treatment for nonsomnolent patients with OSA.[274,414] Notably, these findings may apply less to older adults (age >65). A more recent analysis within this age group has shown increased mortality in older OSA patients only if they exhibit excessive daytime sleepiness.[415] Two recent meta-analyses of observational and randomized studies have not supported a reduction in all-cause mortality in OSA patients using PAP therapy,[371,416] but evidence quality was low due to study type and imprecision regarding measures of PAP adherence that were used. Further studies are needed to delineate further whether some groups derive mortality benefits from PAP therapy.

The association between OSA and mortality is more questionable among individuals over the age of 65.[417] Indeed, Lavie et al. showed a survival *advantage* in elderly patients (≥65 years) with RDIs (similar to AHI) between 20 and 40 events/h; OSA has been hypothesized to be protective in this group due to ischemic preconditioning, leading to increased vascular endothelial growth factor (VEGF) and collateral coronary vessels.[418,419] A subsequent study observed significantly increased mortality rates are among elderly people with severe OSA (AHI ≥30 events/h), and normalization of the mortality rates with CPAP treatment.[176] Debate about whether OSA evaluation and treatment for elderly patients leads to any mortality benefit continues.

Economic Consequences of OSA

Because it is so common, sleep apnea poses a sizeable economic burden on society. OSA subjects have been demonstrated to utilize healthcare resources at approximately 1.5 to 2 times the rate of controls as far back as 10 years prior to diagnosis.[420–423] Estimates of the total economic cost that sleep apnea confers upon society are sparse. However, the financial burden of moderate to severe OSA in the United States is estimated to be $65 to $165 billion/year, which is greater than asthma, stroke, heart failure, and hypertensive disease ($20–$80 billion).[424,425] The economic burden of undiagnosed OSA patients alone is estimated at over $149 billion, highlighting the need for enhanced OSA screening and diagnosis pathways.[426] One way to ameliorate this burden may be through the use of PAP therapy. A recent analysis of Medicare beneficiaries showed that full adherence to PAP treatment (PAP use ≥4 h/night, >70% of nights) is associated with less increase in healthcare costs over time than in subjects with lower PAP adherence.[427]

Limited numbers of sleep laboratories, sleep physicians, and sleep technologists coupled with cost of equipment and reimbursement issues have created a “bottleneck” effect in which global demand for sleep medicine services exceeds capacity. Nevertheless, economic analyses have shown that addressing diagnosis and treatment of moderate to severe sleep apnea, particularly with CPAP, is economically attractive and supports the value to society relative to accepted treatment for other common conditions such as hypertension control, breast cancer screening, and comprehensive diabetes care.[428–433]

TREATMENT OF OSA

The decision to treat OSA should be based on its severity, related symptoms, and medical comorbidities. Treating moderate to severe disease (defined as AHI ≥15), particularly with PAP therapy, improves neurobehavioral performance, enhances quality of life, and may reduce cardiovascular risk.[434,435] In addition to OSA severity, disease-related sleepiness (or lack thereof) has been identified as a treatment determinant. Only sleepy patients with mild to moderate OSA show functional improvement using PAP, although the effect may be small.[436,437] Moreover, nonsleepy patients may not experience significant BP or cardiovascular event rate reduction on PAP, regardless of OSA severity.[131,243,358,438] The AASM currently recommends PAP for OSA patients with excessive daytime sleepiness, reduced sleep-related quality of life, and hypertension.[439] However, for nonsleepy adults with OSA, the AASM concluded there is insufficient evidence to either recommend or withhold PAP and recommended that the patient and clinician have a balanced discussion to decide whether treatment to potentially mitigate cardiovascular risk should be initiated.[439]

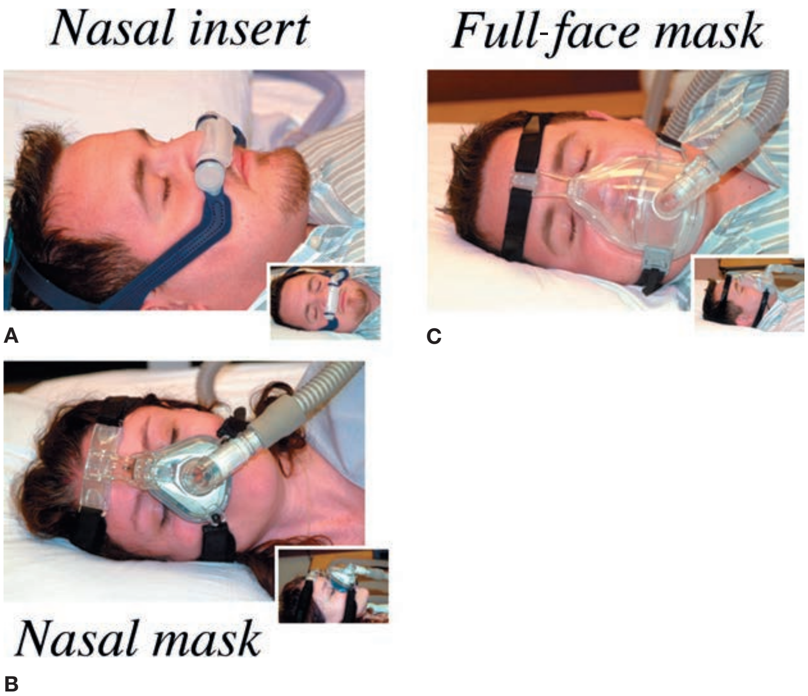

Figure 98-15 Examples of three types of CPAP interfaces. **A.** The subject is wearing a nasal pillow that fit directly into the nostrils. **B.** The subject is wearing a nasal CPAP mask. **C.** The subject is wearing a full-face mask (nose and mouth are both covered). With all three types of interfaces it is essential to ensure a good seal with minimal leaks.

Third-party payers have utilized these data in creating treatment coverage structures. The Centers for Medicare and Medicaid Services cover at least the initial 12 weeks of PAP therapy in patients whose AHI or RDI is at least 15 events/h. Patients with indices of at least 5 events/h but no more than 14 events/h must have documented excessive daytime sleepiness, impaired cognition, mood disorders or insomnia, hypertension, ischemic heart disease, or history of stroke to qualify for PAP coverage.[440] Ultimately, provider expertise should dovetail with patient preference to guide treatment choice and modality.

Options for the treatment of OSA include PAP therapy, behavioral therapies, mandibular repositioning devices, surgical treatments, and adjunctive therapies.[27] First-line therapy for sleep apnea syndrome remains medical.

■ Positive Airway Pressure Therapies

Sullivan et al.[10] first described the use of nasal CPAP to treat OSA in 1981 (see examples of subjects wearing CPAP in Fig. 98-15). Today, CPAP remains the mainstay of therapy for most patients with OSA. CPAP delivers a fixed pressure continuously throughout inspiration and expiration, providing a pneumatic splint for the airway that prevents airway collapse during sleep, when upper airway muscle dilator activity is reduced. CPAP therapy increases airway caliber in the retropalatal and retroglossal regions (Fig. 98-16); in particular, it increases the lateral dimensions of the airway and thins the lateral pharyngeal walls.[441]

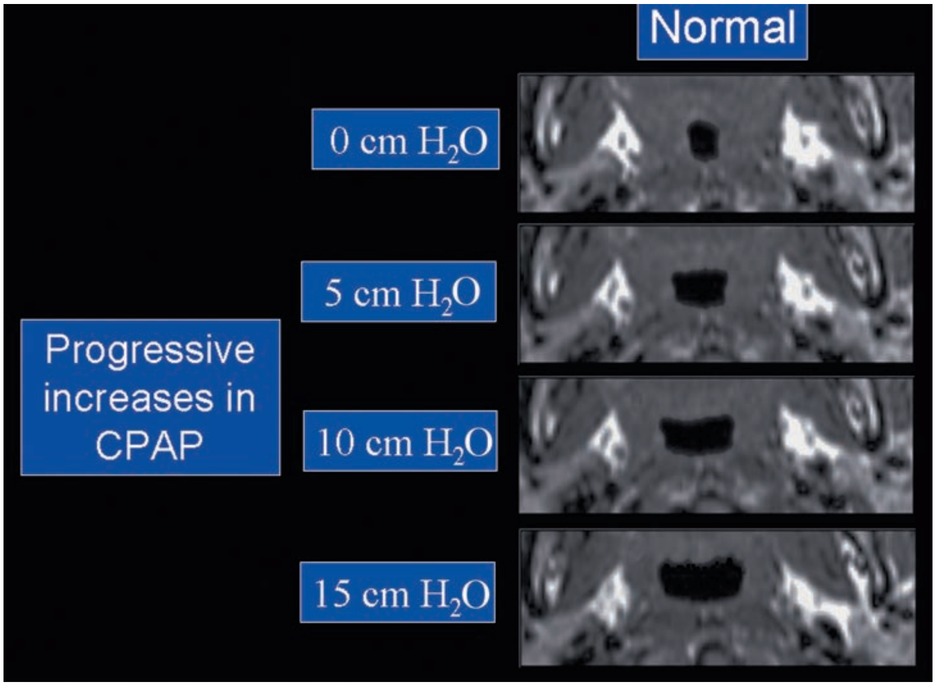

Figure 98-16 Axial retropalatal magnetic resonance imaging (MRI) in a normal individual with continuous positive airway pressure (CPAP) ranging from 0 to 15 cm H_2O. With increasing CPAP there is a progressive increase in the size of the upper airway, particularly in the lateral dimension. (The anterior–posterior dimensions of the airway do not change significantly with CPAP.) There is little movement of the parapharyngeal fat pads (white structures lateral to the airway) but progressive thinning of the lateral pharyngeal walls. *(Reproduced with permission from Schwab RJ, Pack AI, Gupta KB, et al. Upper airway and soft tissue structural changes induced by CPAP in normal subjects. Am J Respir Crit Care Med. 1996;154(4 Pt 1):1106–1116.)*

CPAP usually reduces the number of apneic episodes during sleep to the normal range and has the advantage of being noninvasive. It clearly improves daytime sleepiness in patients with OSA in numerous studies including those in which patients were randomized to CPAP or sham (subtherapeutic) CPAP therapy, with greater improvements in daytime sleepiness among those with the highest AHIs.[436,437,439,442] While there have been many randomized controlled trials published examining the effect of CPAP therapy on blood pressure,[443] CPAP use is associated with only a modest reduction in BP in the range of 2 to 4 mm Hg. This effect seems to be impacted by the underlying severity of OSA, the degree of daytime sleepiness, and the number of hours of nightly use of CPAP therapy.[355,371,444–446] In addition, drivers with OSA who are treated with CPAP have a reduced risk of motor vehicle crashes.[447]

CPAP therapy is indicated in all patients with obstructive sleep apnea (i.e., an AHI $\geq$5 events/h) who are sleepy, report sleep-related quality of life changes, and have comorbid hypertension.[371] The optimal pressure can be determined during a titration polysomnogram or using out-of-laboratory treatment algorithms with auto-adjusting CPAP.[439] Typically, pressures of 5 to 20 cm H_2O are needed to abolish apneic events, snoring, and oxyhemoglobin desaturation in all positions and during REM sleep.

CPAP can be delivered using a variety of interfaces (Fig. 98-15) including nasal masks, nasal inserts, or full-face masks (which cover the nose and mouth). It is important to ensure that the patient has a well-fitting interface with the CPAP machine absent of air leaks. Mask leak is measured directly by the PAP unit, and information on the degree of leak can be obtained from the CPAP machine and reviewed remotely by the provider. Similarly, patients can receive feedback about mask leak directly from their unit or from a mobile application to allow for adjustment to improve mask fit in real time. Mouth leaks, which often result from mouth breathing while using a nasal mask, can render CPAP ineffective, since the positive pressure generated by the CPAP unit escapes. Use of heated humidity with CPAP therapy has been shown to successfully ameliorate some of the side effects listed in Table 98-6. Some but not all studies have demonstrated improvements in CPAP adherence with the use of heated humidification.[448–450]

Over time, CPAP machines and masks have become increasingly user friendly. CPAP masks have improved profoundly, so that the prospect of using CPAP has become much less daunting. Some institutions operate “mask clinics” concomitantly with sleep clinics so that patients with OSA can be fitted for a CPAP interface immediately after the sleep specialist consultation. CPAP units are also smaller, more portable, and quieter, and they now nearly universally provide data on patient adherence patterns, mask leaks, and the effectiveness of the delivered CPAP pressure (i.e., residual SDB events with use of CPAP). Most modern CPAP devices automatically upload this usage data directly to a secure, cloud-based storage system on a regular basis. These data provide critical clinical information to be interpreted by sleep medicine providers. In addition to addressing mask leak, providers can also make pressure adjustments if the residual AHI is noted to be greater than 10 events per hour in a patient who has symptoms or if the residual AHI is greater than 20 events per hour.[451]

TABLE 98-6 Complications Associated with Positive Airway Pressure (PAP) Therapies

Nocturnal arousals
Rhinitis, nasal irritation, and dryness
Aerophagia
Mask and mouth leaks (dry mouth in morning)
Facial rash or irritation
Difficulty with exhalation
Claustrophobia

CPAP use is associated with few serious side effects.[452–455] Common side effects are listed in Table 98-6. Nasal irritation and rhinitis are treated with heated humidification and consideration of a nasal steroid spray. Claustrophobia may be relieved in some cases by changing the type of mask. Aerophagia can be ameliorated by altering body position or mask type. Serious adverse effects are uncommon but include very rare reports of severe epistaxis, meningitis, and pneumocephalus.[456–458]

Like other chronic therapies, there are issues with adherence to CPAP. Currently, insurance rules often require demonstration of adherence defined as >4 h/night for 5/7 nights/week by the 90th day of institution of therapy. With this rule in place, short-term adherence is good. A big-data study of 2.62 million patients showed that 75% met this criterion; participants used CPAP for a mean of 93% of nights.[459] The mean daily use was 5.1 ± 2.5 (SD) h across all nights and 6.0 ± 2.0 h for nights CPAP was used. Approximately 65% to 80% of patients who start CPAP therapy continue to use it after 4 years.[460,461]

While estimates suggest that patients use CPAP treatment, on average, for only 4 to 5 h per night, a dose–response relationship has been observed between longer durations of nightly use and greater likelihood of achieving normal daytime alertness and functional status.[462] Studying methods to enhance CPAP adherence has been an active area of inquiry,[463,464] and multiple methods have been employed and evaluated. Techniques employed include patient education and behavioral interventions such as motivational enhancement.[464] The latter has been studied in randomized trials.[465,466] In one study CPAP adherence was improved by an average of 99.0 min/night at 6 months after starting CPAP.[465] Authors of a Cochrane Review came to the conclusion that behavioral therapy produces a considerable improvement in adherence to CPAP.[467]

Modern CPAP machines collect CPAP adherence and efficacy information daily. This information can be obtained remotely since CPAP machines can have modem or Bluetooth capabilities. The information transmitted on a nightly basis are the hours of use, mask leak, and residual apnea–hypopnea index. CPAP manufacturers maintain cloud-based servers that store the data. These data can be accessed by providers, including the DME companies. Feeding back information on actual compliance to CPAP to patients themselves enhances CPAP use.[468] The ready availability of data from CPAP machines allows other innovative approaches. Telemedicine-automated feedback to patients based on their adherence data also improves short-term adherence to CPAP.[469] It is likely that with enhanced digital technology we will see wider application of this type of approach in the future.

In addition to fixed CPAP, PAP can be delivered via automatically titrating systems and bilevel systems. Autotitrating CPAP, or auto-CPAP, adjusts CPAP during use by detecting airway flow, snoring, apneas, and inspiratory flow limitation (Fig. 98-17). Each auto-CPAP unit uses a different algorithm for abolishing apneic events. These algorithms are currently proprietary, that is, only the manufacturers have information on the specific algorithms. These units can be utilized in several ways: for chronic treatment of OSA (e.g., for patients with difficulty tolerating fixed CPAP and evidence of variable positive pressure needs due to REM-related or positional sleep apnea); or for use in the laboratory or at home to determine the optimal setting for conventional fixed CPAP after a trial period.[470] Patient adherence does not appear to be significantly improved with chronic use of auto-CPAP compared with fixed CPAP therapy.[471]

The use of auto-CPAP for OSA titration is associated with substantially lower costs compared to in-laboratory CPAP titration, and

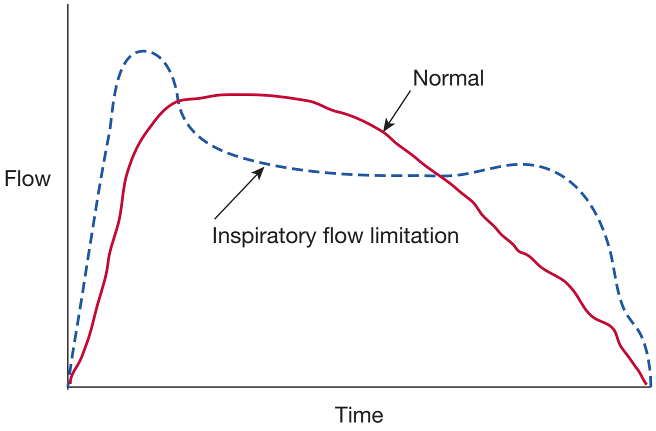

Figure 98-17 Schematic diagram showing the normal pattern of airflow during inspiration and that which occurs when there is inspiratory flow limitation. In the latter the flow quickly reaches a level that is maintained relatively constant throughout inspiration. This pattern of airflow can be detected by processors built into auto-CPAP units.

a number of studies have shown that auto-CPAP can be successfully incorporated into algorithms for diagnosis and treatment of OSA. Furthermore, with the greater implementation of out-of-laboratory treatment algorithms in which patients undergo portable monitoring for OSA diagnosis and are then started and maintained on auto-CPAP therapy, utilization of auto-CPAP has become increasingly common.[472,473] While results from one trial comparing fixed pressure CPAP to auto-CPAP suggest that fixed CPAP may be more effective at lowering 24-h diastolic blood pressure,[474] most studies to date have not demonstrated significant differences between the effects of auto-CPAP and fixed-pressure CPAP on blood pressure.[475–478]

Bilevel systems deliver higher pressures during inspiration and lower pressures during expiration and may be used when patients report difficulty with exhaling against PAP. However, bilevel systems are more expensive and evidence of better adherence and treatment outcomes when compared with CPAP is lacking.[479,480] Limited evidence suggests that patients with coexisting lung disease or respiratory acidosis demonstrate improved gas exchange with the use of bilevel PAP compared with CPAP.[481]

■ General Measures

Patients with sleep apnea should avoid alcohol, sedative hypnotics, and opioids.[482] These commonly used substances are generally thought to reduce upper airway muscle tone and increase the severity of snoring and apneas.[123,483–487] They may also depress arousal mechanisms, thereby prolonging apneas and causing more profound oxygen desaturations.[484,485,487]

Adherence to good sleep hygiene practices in order to maintain an adequate amount of sleep is also important in patients with sleep apnea. Sleep deprivation may reduce hypoxic and hypercapnic respiratory drive and prolong apnea duration.[488–491]

■ Weight Loss

Excess weight theoretically increases the propensity for upper airway collapse due to higher extraluminal pressures associated with excess soft tissue and/or fat and the encroachment of the tongue and soft palate.[54,492] Truncal obesity may also play a role by reducing chest compliance and functional residual capacity; this leads to increased oxygen demand.[493] Weight loss via dietary modification has been associated with significant reductions in SDB.[494,495] The extent of weight loss and degree of improvement are not always directly related, although it has been shown on average that a 1% change in weight is associated with a 3% change in AHI.[496] More specifically, weight loss in obese patients with type 2 diabetes mellitus is associated with a significant reduction in AHI.[497] Interestingly, AHI changes associated with weight loss (or weight gain) are stronger in men than women.[498] Weight loss effects on OSA can be beneficial well into the weight maintenance phase.[499–501]

Over the past several years, there has been progressive interest in the use of bariatric surgery to treat extreme obesity. Bariatric surgery is considered for individuals with BMI ≥35 kg/m^2 (≥32.5 kg/m^2 in Asians) who have OSA or other obesity-related conditions.[502] At present, the majority of bariatric procedures performed in the United States are sleeve gastrectomy (61%), followed by Roux-en-Y gastric bypass (17%)[503]; in randomized trials, patients undergoing these procedures manifest similar degrees of weight loss.[503] Across 24 nonrandomized controlled trials and 3 randomized controlled trials in which bariatric surgery was compared to various therapies including intensive lifestyle intervention, intensive nutritional care and CPAP, all studies consistently showed significant falls in weight and AHI following bariatric surgery both individually and when included in a recent metanalysis.[504] Over the 10 studies in which daytime sleepiness was assessed, there was also a significant improvement in Epworth Sleepiness Scale scores.[504] Nevertheless, while bariatric surgery is the most effective treatment for obesity and thus can lead to the greatest reduction in AHI among individuals with OSA, OSA did not completely resolve in the majority of patients examined 1 year after undergoing bariatric procedures.[504] Tongue fat may provide a critical link between obesity and OSA, as changes in tongue fat volume have been shown to mediate the relationship between weight loss and reductions in AHI.[166]

Given the available data, individuals who undergo bariatric surgery and experience a significant amount of weight loss should be formally reassessed for the presence of sleep apnea after maximal weight loss has been achieved. The use of autoadjusting CPAP should be considered during the postoperative period to accommodate changes in SDB during this time. Of note, increased hours of weekly physical exercise appear to have a beneficial effect on the incidence of mild to moderate OSA; this effect appears to be related to changes in body habitus.[505] It should be noted that SDB can, in turn, promote obesity via several mechanisms including physical inactivity due to sleepiness; poor dietary habits related to abnormalities in leptin, a satiety hormone; insulin resistance; and systemic inflammation.[161,333,391,506–517] Given these findings, weight loss should be recommended in all overweight and obese patients with OSA.

Of interest, a secondary analysis of data from the APPLES study revealed that individuals using CPAP experienced modest weight gain compared with those using sham CPAP,[518] an observation supported by subsequent studies.[519] An overall decrease in basal metabolic rate and increase in calorie intake have been observed among individuals who gained weight after CPAP initiation, suggesting that a positive energy balance is a possible mechanism of weight gain during OSA treatment,[520] and that untreated OSA affects energy metabolism through elevated resting metabolic rate and sleeping energy expenditure.[521]

More recently, a new medical approach to obesity has focused on the response to treatment with glucagon-like peptide 1 receptor agonists (GLP-1 Ras), particularly GLP-1 Ras with longer half-lives such as semaglutide.[522] These medications stimulate insulin secretion and reduce glucagon production from pancreatic cells and may also delay gastric emptying.[522] The mechanism of weight loss appears to be related to decreasing hunger and cravings for high-fat foods.[523] A recent, randomized, double-blind, parallel-group, phase 3a study looked at the additional benefit of semaglutide to intensive behavioral therapy and low-calorie diet. When compared with placebo, once-weekly subcutaneous semaglutide resulted in a

10.3% greater increase in body weight and more participants lost at least 5% of their body weight (86.6% vs. 47.6%).[524] This effect was sustained for 68 weeks.[525] At present, there are no data on the impact of weight loss using weekly-dosed GLP-1 Ras on OSA, but daily liraglutide demonstrated reduction in AHI (–6.1 events per hour) which was associated with the degree of weight loss in post hoc analysis.[526]

■ Intraoral Devices

Although CPAP represents the gold standard for treating OSA, adherence can be challenging for many patients.[453,455,527–529] Given this, increasing attention has focused on the use of intraoral devices, also known as oral appliances, as an alternative treatment to CPAP.

Oral devices aim to alter the position of the upper airway structures, thereby enlarging airway caliber and/or reducing airway collapsibility during sleep. Oral appliances have undergone considerable evolution in their design, comfort, and effect on airway structures. The tongue retaining device (TRD) developed in the 1980s by Samelson was designed to maintain the tongue in a forward position during sleep.[530] Given relatively sparse data on TRDs, a recent clinical guideline noted there were insufficient data to assess the efficacy of these devices for treatment of adults with OSA.[531] Two other types of devices are palatal lifting devices and mandibular advancing devices (MAD), the latter being the most studied (see example of mandibular advancing device, Fig. 98-18). The mandibular advancement devices produce downward rotation and advancement of the lower jaw during sleep.[532] These devices are fashioned out of a wide variety of materials and are available with various features. Many MADs are custom-made for the client following a dental or maxillofacial surgery consultation. In choosing an oral device, attention to its adjustability (modifiability over time) and titratability (ability to alter jaw position by adjusting the appliance) are important. In addition, provisions for temporomandibular joint support, tooth coverage, and jaw mobility are important, as side effects of the oral devices include excessive salivation, dry mouth, tooth or jaw discomfort, occlusive changes, and temporomandibular joint pain.[533] Recent advances include the ability to produce these devices using 3D printing techniques.[534]

Historically, there was no mechanism to objectively measure adherence to oral appliance therapy, but this has changed with the recent availability of commercially available temperature microsensors embedded into the device.[534] While studies using microsensor chips have indicated high rates of adherence (>80% for 1 year), sample sizes have been small.[535] Availability of this technology will allow for more robust study of the impact of successful treatment of OSA using oral appliances.

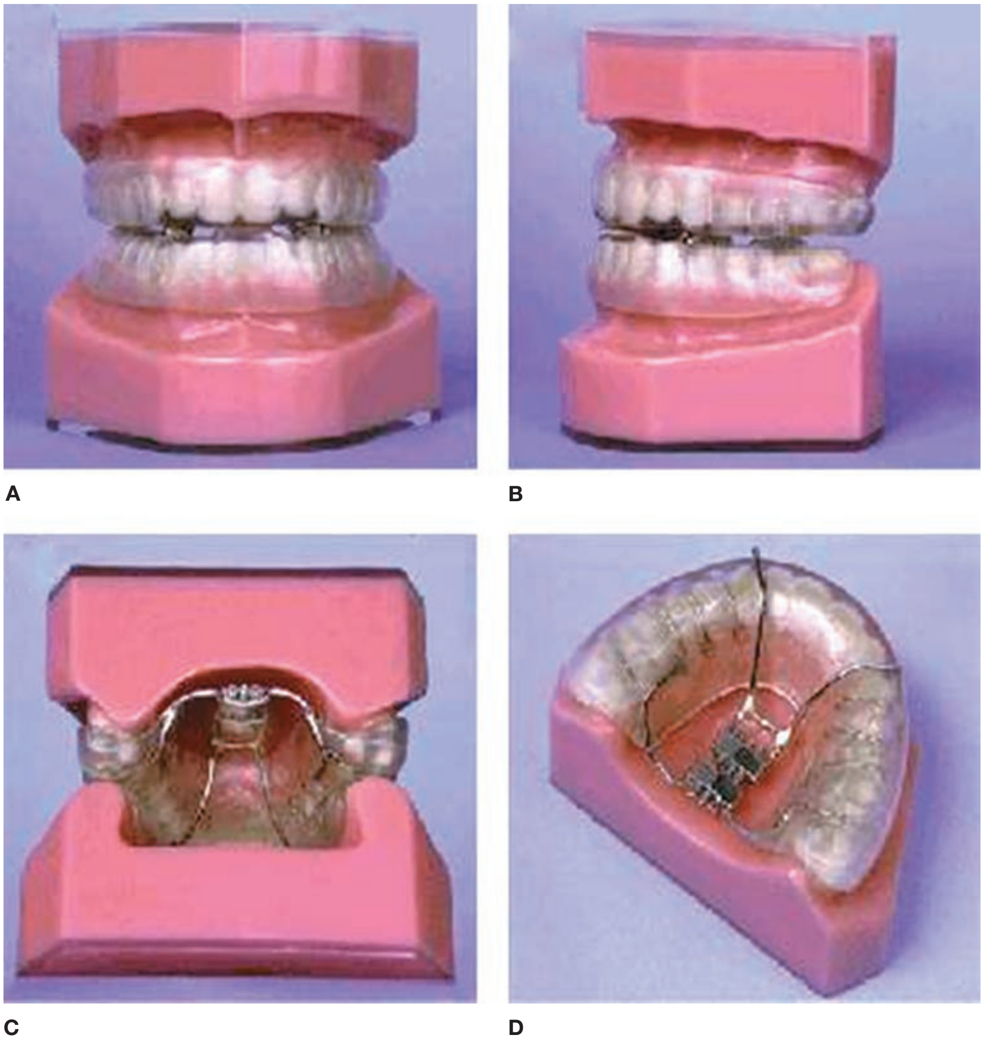

Figure 98-18 Anterior (**A**), lateral (**B**), posterior (**C**), and superior (**D**) views of an adjustable mandibular repositioning device (Klearway appliance, University of British Columbia, Vancouver, Canada). This device fits on the upper and lower teeth; it is worn during sleep and results in anterior motion of the mandible with consequent enlargement of the airway. The appliance is adjusted until the sleep-disordered breathing improves.

A recent systematic review commissioned jointly by the American Academy of Sleep Medicine and the American Academy of Dental Sleep Medicine examining the role of oral appliances (mandibular advancement devices) found that custom oral appliances reduced the frequency of sleep-disordered breathing events (AHI, RDI, REI, or ODI) and modestly improved minimum oxygen saturation in adult patients with OSA.[531] Oral appliances were also shown to reduce the arousal index and to improve daytime sleepiness and quality of life, but to have no significant effect on sleep architecture and sleep efficiency. Compared to CPAP, oral appliances were less effective at reducing SDB events, daytime sleepiness, minimum oxygen saturation, and arousal index, but nearly as effective as CPAP at improving quality of life.[531,536,537] Similarly, while the blood pressure–lowering effect associated with custom oral appliances was modest, it was deemed nearly equivalent to CPAP therapy.[445] Adherence to oral appliance therapy was observed to be higher compared to PAP therapies in a metanalysis of six trials comparing the two treatments, with four of the individual studies demonstrating higher usage of oral appliances.[538]

Based on these data, oral appliances are a reasonable alternative to CPAP, particularly for patients with primary snoring, or those with mild to moderate OSA who prefer an oral appliance to CPAP or do not respond to, are not appropriate candidates for, or fail treatment attempts with CPAP. A recent study identified phenotypic characteristics including lower age, female sex, lower BMI, smaller neck circumference, lower AHI, a retracted maxilla and mandible, a narrower airway and a shorter soft palate that were associated with a good response to oral appliance therapy, and suggested they could be used in clinical practice to identify appropriate candidates.[539] Patients with severe OSA should have a trial of CPAP first based on lower success rates with oral appliances.[531] Patients treated with an intraoral device are recommended to have follow-up sleep testing to verify efficacy, as some patients show no improvement. Importantly, the ability of oral appliances to reduce the severity of SDB to less than 10 events/h has been estimated to be approximately 50%.[533] Furthermore, based on a recently validated technique it is now possible to quantify loop gain directly from routine polysomnography as well as home sleep studies.[540] Using this technique, several studies have identified that low loop gain, higher arousal threshold, moderate pharyngeal collapsibility, and weaker muscle compensation are associated with improved efficacy of oral appliances.[541] Prospective validation suggests airflow testing may be useful for prediction[542]; further research is warranted. Patients started on mandibular advancement devices should be closely monitored by the treating physician to assess for signs and symptoms of worsening OSA. In addition, regular follow-up with the dental specialist who fashioned the device is an important component of ongoing care in patients who utilize oral appliances, to detect problems such as loosening of teeth.

■ Position Therapy

It seems intuitive that body position during sleep would have an effect on respiratory mechanics.[543–545] Sleep in the supine position would seem to be more conducive to airway obstruction by virtue of gravity's effect on the tongue along with higher collapsibility of the airway in the supine vs. nonsupine position.[546] Raising the head of bed angle to between 30 and 60 degrees has been studied; however, it is unclear if its effects reach beyond promoting airway stability to actually reducing AHI.[543,544,547] In 1984, Cartwright defined positional-dependent sleep apnea as SDB in which the AHI while asleep in the supine position was at least twice as high as in the lateral position.[548] The prevalence of position-dependent sleep apnea using this definition may be as high as 50% to 70% and may be of particular significance in patients with mild OSA.[549–554]

For patients with position-dependent sleep apnea, symptoms may be alleviated by promoting sleep in the lateral decubitus position.[552,555–560] The lateral position is associated with increased maximum cross-sectional upper airway area and lower closing pressure of the passive pharyngeal airway compared to the supine position.[545] Lateral positioning during sleep initially focused on the use of a bulky item, such as a tennis ball, placed on the patient's back.[561,562] These techniques appear to be effective in reducing the percentage of total sleep time in supine position and the overall AHI, but the long-term compliance rate is only 10%.[563–566,791] This is due to back discomfort and no improvement, or even deterioration of sleep quality and/or daytime alertness.[563,566] Next-generation position therapy in the form of a vibrational alarm worn on the trunk or neck delivers a vibrating stimulus to gently wake the patient when they move to the supine position. A meta-analysis demonstrated a reduction in both the AHI and the percentage of TST in the supine position.[567] Long-term compliance with a vibrational alarm appears to be higher at 1 year than with the bulky mass technique.[568]

Several studies have suggested that positional therapy is equivalent to CPAP in the treatment of positional-dependent sleep apnea.[552,565] However, a Cochrane review concluded that in terms of reducing the AHI and increasing oxyhemoglobin saturation, positional therapy was inferior to CPAP therapy. In addition, long-term compliance for positional therapy appears to be mediocre at best; nonetheless it is better than adherence to CPAP therapy, although there was no difference in the ESS or quality of life between the groups.[569] Interestingly, use of positional therapy in combination with another therapy for position-dependent OSA, such as a mandibular repositioning device, may be associated with a greater reduction in AHI.[570–572] Given all that is known about positional therapy, a relatively simple and inexpensive technique, consideration of its use to treat mild OSA with a positional component or as an additive measure to improve the efficacy of other treatment measures is warranted.

■ Nasal Expiratory Positive Airway Pressure

Nasal expiratory positive airway pressure (EPAP) is delivered via a novel device with a one-way mechanical valve that provides high expiratory resistance in the setting of very low inspiratory resistance. The nasal EPAP device is placed within each nostril during sleep and can be used for up to three months before needing replacement (*www.accessdata.fda.gov/cdrh_docs/pdf18/K180619.pdf*). Positive pressure resulting from the high expiratory resistance during exhalation stents open the upper airway, rendering it less likely to collapse on subsequent inhalation, and increases end-expiratory lung volumes.[573,574] Nasal EPAP appears to reduce AHI and improve subjective sleepiness in patients with mild to moderate OSA.[575–577] Nasal EPAP has not yet been compared with CPAP directly. A recent study assessing the utility of nasal EPAP as an alternative short-term therapy for patients with moderate to severe OSA already on therapeutic CPAP was unable to show a beneficial effect of nasal EPAP.[578] Given our current knowledge, it is unclear if nasal EPAP should be considered as an alternative therapy in individuals with mild to moderate SDB who are unable to tolerate CPAP therapy.

■ Surgical Treatment of OSA

A variety of surgical treatments have been employed in management of OSA and are discussed below.

Hypoglossal Nerve Stimulation

The genioglossus muscle is the largest airway dilator muscle. Electrical stimulation of the hypoglossal nerve causes tongue protrusion and stiffening of the anterior pharyngeal wall.[579] Attempts at muscle stimulation enlarged the upper airway diameter and reduced apneas and hypopneas during sleep in patients with SDB.[580–585] However, use of this technique has been limited by arousals associated with tongue protrusion.[585–587] An alternative strategy is to electrically stimulate the hypoglossal nerve to cause contraction of the genioglossus muscle, thereby increasing lower and upper airway patency during sleep in properly selected patients.[72,588–590] The branches of the hypoglossal nerve that innervate the genioglossus consist mostly of efferent (motor) fibers that activate the genioglossus muscle with minimal sensory feedback.[579] Chronic stimulation of the hypoglossal nerve as a possible treatment for OSA was initially considered more than 25 years ago, but several technical limitations led to a 10-year hiatus before enthusiasm for hypoglossal nerve stimulation (HGNS) resurfaced.[579,591–594] In a large, multicenter, prospective, single-group cohort study of carefully selected patients (STAR cohort), HGNS was associated with improvements in AHI (decreased by 68%), oxygen desaturation index (ODI; decreased by 70%), subjective sleepiness measured by Epworth Sleepiness Scale, and quality of life, as well as with high adherence (84%).[72] The primary outcome cohort study was followed by a randomized, controlled, therapy-withdrawal study consisting of the first 46 consecutive participants who were noted to have a response to therapy. Subjects were randomly assigned to the therapy-maintenance group or the therapy-withdrawal group. In this select group of responders to HGNS, therapy withdrawal was associated with a significantly higher AHI and ODI that subsequently improved when therapy was restarted.[72,589] Five-year follow-up data indicate improvements in AHI, sleepiness, and quality of life that persist in the long term.[595] Serious adverse events are uncommon. Several systematic reviews of cohort studies have demonstrated efficacy in patients with moderate to severe OSA treated with HGNS, including reduced AHI, reduced ODI, and improved sleepiness and quality of life.[588,596–598]

Early evidence indicates that HGNS may lead to improvements in downstream consequences of OSA. In the original STAR cohort, responders to HGNS were noted to have reduced heart rate variability.[599] A retrospective study comparing treatment with HGNS to PAP therapy found PAP lower mean arterial pressures in all patients, whereas HGNS lowered mean arterial pressures only among patients with elevated BP at baseline.[600] In nondiabetic patients, HGNS was associated with improved insulin resistance and oral glucose tolerance.[601]

Although current U.S. Food and Drug Administration (FDA) approval includes specific eligibility criteria (*www.fda.gov/medical-devices/recently-approved-devices/inspirer-upper-airway-stimulation-p130008s039*)—including moderate to severe OSA (AHI $\geq$15 and $\leq$65 events/h), BMI $<$33 kg/m^2, inability or unwillingness to use PAP therapy, and absence of complete concentric collapse at the palate on DISE exam—recent studies suggest that additional patients (e.g., AHI $>$65 events/h and BMI $>$32 kg/m^2) also may benefit from treatment with HGNS.[590,602–606]

Upper Airway Corrective Surgery

A variety of surgical options are available to correct abnormalities in the upper airway that lead to obstruction during sleep (Table 98-7). However, the success of these treatments, aside from tracheostomy, is less well established and generally less effective than PAP therapy.[413] The leading objective for presurgical evaluation is to identify the primary site(s) of obstruction. The level of obstructive site influences the type of surgical procedure to be performed. Fiberoptic laryngoscopy, drug-induced sleep endoscopy, or imaging can be used to classify the obstruction of the airway at the nasal, oropharyngeal, and/or hypopharyngeal level.[607,608] Surgeries aimed at reducing obstruction at the nasal, palatal, and lingual levels are referred to as phase 1 surgeries. They are typically performed first with subsequent use of a phase 2 surgery such as maxillomandibular advancement (MMA) when needed.[413]

Tracheostomy is virtually 100% effective in eliminating obstructive apneas.[609] Despite its high efficacy, it requires changes in lifestyle and is associated with negative impact on patients' quality of life. Tracheostomy is generally reserved for patients with severe OSA who have failed medical or surgical therapy and who manifest severe complications such as malignant arrhythmias without treatment.[610] Tonsillectomy and adenoidectomy is the primary therapy for children with OSA; however, it is not usually successful in adults.[611]

TABLE 98-7 Surgery for Obstructive Sleep Apnea

Nasal surgery (septoplasty, sinus surgery, and others)
Tonsillectomy ± adenoidectomy
Hypoglossal nerve stimulator implantation
Uvulopalatopharyngoplasty (UPPP)
Laser-assisted uvulopalatoplasty (LAUP)
Radiofrequency volumetric tissue reduction
Lingular tonsillectomy
Genioglossus and hyoid advancement (GAHM)
Sliding genioplasty
Maxillomandibular advancement osteotomy
Tracheostomy

Maxillomandibular advancement surgery enlarges the upper airway by physically expanding the facial skeletal framework.[612] While this invasive procedure is usually considered only for carefully selected patients whose OSA has been refractory to CPAP and other surgical interventions, a recent metanalysis incorporating data from 518 patients across 45 studies reported mean reductions of AHI and RDI of 80.1% and 64.6%, respectively, with 64.7% of patients with available AHI data demonstrating a reduction to fewer than 10 events/h.[612] Lower preoperative AHI was the only factor significantly associated with surgical cure in multivariable analyses.[612] Nevertheless, MMA should be considered only in patients with severe OSA in whom PAP therapy and oral appliance therapy are ineffective[610] and probably should be avoided in morbidly obese individuals until more information on its efficacy is available in this population.[612]

Another procedure, uvulopalatopharyngoplasty (UPPP) with tonsillectomy, was noted in a recent metanalysis to be associated with a 46.1% initial decrease in AHI. However, the surgical response rate was observed to decrease from 67.3% to 44.35% over the longer term (i.e., $\geq$34 months after surgery).[613] Another meta-analysis found that this relapse in AHI begins soon after the procedure, with a mean increase in AHI of 1.45 events/h per month over a mean follow-up period of 8.18 months. Furthermore, UPPP does not have a consistent effect on AHI when performed as a sole surgical procedure, and therefore it cannot be recommended as a standalone treatment for OSA.[614]

The role of other phase 1 therapies remains unclear. Laser-assisted uvulopalatoplasty (LAUP), a procedure involving removal of the uvula and a part of the soft palate with a carbon dioxide laser, has been associated with worsening of AHI among 44% of patients and a cure rate of only 8%[615]; it is not recommended as a treatment option for OSA by the AASM.[610] Radiofrequency volumetric tissue reduction (i.e., radiofrequency ablation [RFA]), a minimally invasive technique, has been employed to treat turbinate hypertrophy and to reduce the size of the base of the tongue. Palatal implants are intended to stiffen the soft palate and protect against upper airway collapse. Only modest improvements in symptoms and AHI were noted in one randomized controlled trial.[616] In part because of their relatively low surgical risk, RFA and soft palatal implants can be considered in individuals with mild to moderate OSA who have found CPAP and oral appliance therapy ineffective and/or undesirable.[610]

Genioglossus advancement with hyoid myotomy involves movement of the tongue forward without moving the mandible, with the aim of achieving a larger-caliber airway. The success of such combinations has been variable, ranging from 23% to 77%.[617–621] Because of inconsistent results in the setting of increased surgical risks, genioglossus advancement and related surgeries are presently not recommended therapies for OSA.

A number of recent studies have examined the value of performing UPPP and other surgical interventions for OSA compared to transoral robotic surgery.[792] In general, no significant differences have been observed in metrics including AHI, oxygen saturation nadir, ESS scores, and complication rates between patients receiving robotic surgery groups and other interventions.[622]

Other procedures listed in Table 98-7 are designed to increase airway caliber or to improve CPAP compliance. Treatment of nasal obstruction by surgical means has proved helpful in some patients, especially by allowing the patient to better tolerate CPAP. The most common nasal surgical procedure is septoplasty and turbinate reduction. These procedures can lead to subjective improvement in nasal patency and a reduction in nasal CPAP pressure requirement.

Surgery represents a viable therapeutic option for carefully selected OSA patients who cannot tolerate PAP therapy or an oral appliance. The growing use of hypoglossal nerve stimulation has further reduced the use of other surgical procedures. Meticulous preoperative assessment by examination, nasopharyngoscopy, and radiologic imaging can help to identify the likely area of upper airway obstruction. If a surgical procedure is performed, close follow-up in the immediate postoperative period to assess treatment response as well as long-term follow-up to monitor for recurrence of disease are warranted.[610]

■ Oxygen Therapy

Oxygen has a limited role in the treatment of sleep apnea syndrome. Chronic hypoxemia is associated with reduced hypoxic and hypercapnic ventilatory drives.[623] Although oxygen desaturation may be mitigated by the delivery of oxygen, there is some evidence that administration of supplemental oxygen may increase the arousal threshold and thereby prolong apneic events.[624] In this same study of three patients, supplemental oxygen use was also associated with worsening respiratory acidosis.[624] However, subsequent studies with larger numbers of subjects demonstrated that the use of supplemental oxygen reduced the degree of oxyhemoglobin desaturation and improved or did not worsen apnea frequency or duration.[623,625–628] Among patients with a relatively unstable ventilatory control system and high overall loop gain, supplemental oxygen may stabilize ventilation, reducing AHI.[629,630] The effect of supplemental oxygen alone on blood pressure in patients with OSA was examined in a randomized controlled trial of individuals with an AHI of 15–50 events/h.[631] After 12 weeks, among participants who were assigned to receive nightly supplemental oxygen (2 LPM), there were no significant differences in 24-h mean arterial pressure or C-reactive protein compared to the control group. While oxygen improves nocturnal oxygen saturation during use without significant adverse consequences, it does not have a clear role in the treatment of OSA.

■ Medications

Several pharmacologic agents have been investigated as possible therapies for primary treatment of OSA. One such intervention showing promise is the combination of atomoxetine and oxybutynin.[632] This pharmacologic pair has recently been shown to reduce AHI significantly in patients diagnosed with OSA, perhaps by enhancing genioglossal muscle responsiveness to upper airway instability. While individuals with reduced upper airway muscle responsiveness (determined by physiologic phenotyping) may be more likely to benefit from pharmacologic treatment,[177] subjects in the atomoxetine-oxybutynin study were not phenotyped. These participants reported more subjective improvement in sleep quality with higher AHI reductions, but no effect on AHI was observed if either medication was taken alone. Further investigation is needed before this combination therapy is more widely utilized.[632]

Unfortunately, few other medications have demonstrated significant effectiveness for treatment of OSA.[633] Specifically, selective serotonergic reuptake inhibitors, protriptyline, methylxanthine derivatives (e.g., theophylline), and estrogen therapy are not recommended.[27,634–636] Of notable exception, patients with hypothyroidism and acromegaly should be treated with thyroid replacement and somatostatin analogues, respectively, as such treatment does improve AHI.[27,634]

While short-acting nasal decongestants have no effect on airway patency in sleep apnea, topical nasal corticosteroids may be useful as adjunctive therapy to treat concurrent rhinitis.[27,635,636] Such treatment may be particularly helpful if rhinitis is exacerbated by PAP therapy despite the use of heated humidification. In addition, there are conflicting data regarding the use of sedative–hypnotics at the time of CPAP initiation.[637–640]

Stimulants such as modafinil can be utilized as adjunctive therapy for residual sleepiness in patients who remain excessively sleepy despite adequate treatment for SDB.[635] Doses ranging from 200 to 400 mg daily have been shown to be effective in improving excessive daytime sleepiness in several randomized trials.[641–645] Treatment with modafinil should be undertaken only after a careful search for alternative causes of residual sleepiness has been performed.[27]

CENTRAL SLEEP APNEA SYNDROMES

CSA, in which repetitive episodes of breathing cessation occur in the absence of respiratory effort, is characterized by reduced ventilatory motor output (Fig. 98-19). CSA is much less common than OSA, with one study estimating the prevalence in the general population to be <1%. Even in the clinical sleep laboratory setting, CSA is relatively uncommon.[133,646] However, small disruptions within a number of complex feedback loops in the ventilatory control system can lead to and then sustain CSA. CSA has been described as a physiologic process in normal individuals in response to an arousal (especially children and the elderly), as a manifestation of breathing instability in a number of medical conditions (e.g., Cheyne–Stokes respiration [CSR] in CHF and at high altitude), or in association with neurologic diseases such as Shy–Drager syndrome, stroke, myasthenia gravis, neuromuscular disease, bulbar poliomyelitis, brainstem infarction, and encephalitis.[647–651] It is often divided into hypocapnic and hypercapnic types.[652]

The following discussion focuses on hypocapnic CSA, as the hypercapnic CSA syndromes (e.g., OHS and congenital central hypoventilation syndrome) are discussed elsewhere (Chapter 99). The vast majority (85%–90%) of patients with OHS have concomitant OSA.[40,41] Characteristic findings observed with OHS include awake resting hypoxemia and hypercapnia, hypersomnolence, signs of cor pulmonale (right-sided heart failure and lower extremity edema), and nocturnal hypoventilation. In general, the hypocapnic CSA syndromes are associated with increased chemoresponsiveness of the ventilatory control system and are seen most commonly in individuals with heart failure or at high altitude.

During wakefulness, there is an endogenous drive to breathe that has been termed the *wakefulness stimulus*. With the onset of sleep, withdrawal of the wakefulness stimulus occurs and the chemical drive to breathe predominates.[653] Minute ventilation falls during sleep by 10% to 15% and P_{CO_2} levels rise approximately 2 to 6 Torr.[654–656]

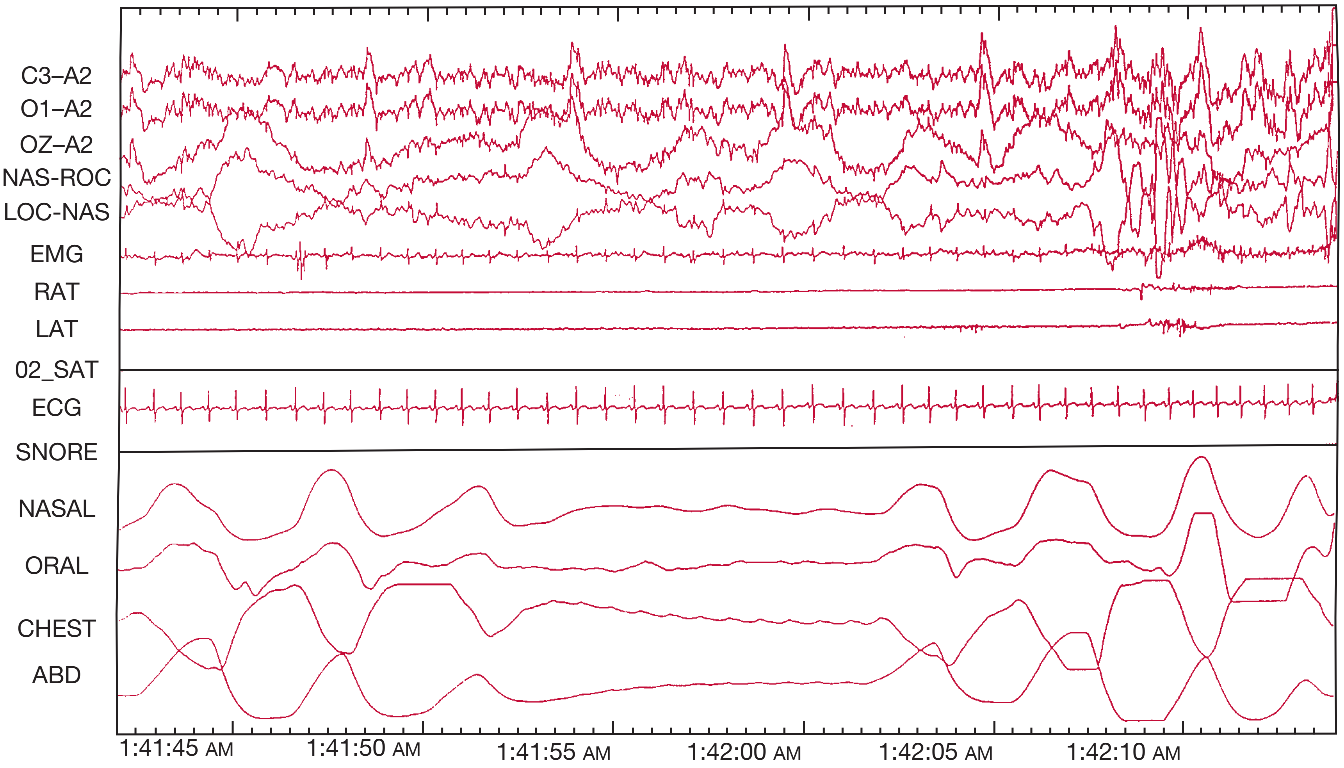

Figure 98-19 Example of central apneas. The polysomnography traces from the top down are as follows: Three EEG channels *(C3, C4, O1)*; two EOG channels *(ROC and LOC)*; submental electromyogram *(EMG)*; right and left anterior tibialis EMG *(RAT and LAT)*, oxyhemoglobin saturation *(SaO$_2$)*; electrocardiogram *(ECG)*; snoring channel *(SNORE)*; nasal airflow *(NASAL)*; oral thermistor *(ORAL)*; and chest and abdominal motion *(CHEST and ABD)*. During the apneic episodes, there is lack of airflow without rib cage or abdominal motion.

Central apneas occur if the arterial P_{CO_2} falls below the "apneic threshold," or P_{CO_2} level necessary to maintain rhythmic breathing.[657] Causes of hypocapnia include sleep-state changes, hypoxia, and fluctuations in minute ventilation related to heart failure.

Other features of the ventilatory control system can promote and sustain recurring central apneas. If the magnitude of the increase in ventilation that occurs in response to changes in P_{CO_2} is larger than is needed to achieve eupnea, self-sustaining oscillations in ventilation in which P_{CO_2} is repeatedly driven to the apneic threshold can occur and manifest as periodic breathing.[658–660] Such oscillations in ventilation can also occur when there is a lag between changes in ventilation and detection of the ensuing effects on P_{CO_2} and P_{O_2} by the central and peripheral chemoreceptors, as occurs when arterial circulation time increases.[661] Recurrent arousals from sleep can also play an important role in initiating and maintaining central apneas as the state change from sleep to wakefulness re-engages the neurogenic drive to breathe.[657,662] This can provoke ventilatory overshoot as P_{CO_2} is driven to the lower P_{CO_2} set point of wakefulness, especially in the setting of continued sleep–wake instability.

■ High-altitude Periodic Breathing

Periodic breathing with hypocapnic central apnea occurs in many healthy individuals at high altitude. At altitude, the peripheral chemoreceptors in the carotid body that sense hypoxia increase ventilatory drive.[663] As P_{CO_2} falls in response, the apneic threshold during sleep is reached, precipitating central apneas and creating a cycle of periodic breathing. Because the delay between changes in P_{CO_2} and P_{O_2} levels and detection by peripheral chemoreceptors is brief, the cycle time of periodic breathing at altitude tends to be short (12–34 s).[664] Poor sleep quality is a frequent complaint at high altitude and is likely to be related to hypoxemia and periodic breathing with frequent arousals.[665,666] Although it seems intuitive that periodic breathing would resolve as individuals acclimate to altitude, observations of decreases, increases, and lack of change in periodic breathing have all been reported.[667–670] Gender differences in high-altitude periodic breathing also have been described, with significantly fewer central sleep apnea events among women compared to men at 3400 and 5400 meters, and significantly longer respiratory cycles in women.[671] High-altitude periodic breathing can be treated using acetazolamide, which increases the magnitude of the change in P_{CO_2} required to produce central apneas, that is, it alters the apneic threshold.[672] Use of supplemental oxygen improves high-altitude periodic breathing and sleep quality and thus should also be considered.[673,674]

■ Cheyne–Stokes Respiration (CSR)

CSR is most commonly seen in individuals with systolic heart failure and, especially when present during wakefulness, is a risk factor for higher mortality in this population.[675–677] CSR is also observed in individuals with encephalopathies, stroke, and other conditions.[678–680] Among individuals with systolic heart failure, male gender, age greater than 65, atrial fibrillation, and awake hypocapnia (P_{CO_2}<38 mm Hg) all increase the risk for CSR.[681] Despite speculation that the prevalence of CSR has declined with the use of beta blockers for treatment of CHF, two studies indicate that the prevalence of SDB in general, and CSR in particular, remains high in this population.[682–684]

CSR is characterized by prolonged hyperpneas with a waxing and waning respiratory pattern and prolonged cycle duration, that is, 40 to 90 s (Fig. 98-20). Although CSR can occur during wakefulness, it is much more common during sleep, especially during non-REM sleep, when ventilation is predominantly under metabolic control and thus particularly sensitive to the apneic threshold and changes in P_{CO_2}.[685,686] Greater peripheral and central chemoresponsiveness among individuals with heart failure and CSR promotes hyperventilation and hypocapnia.[660,687] The timing and role of arousals

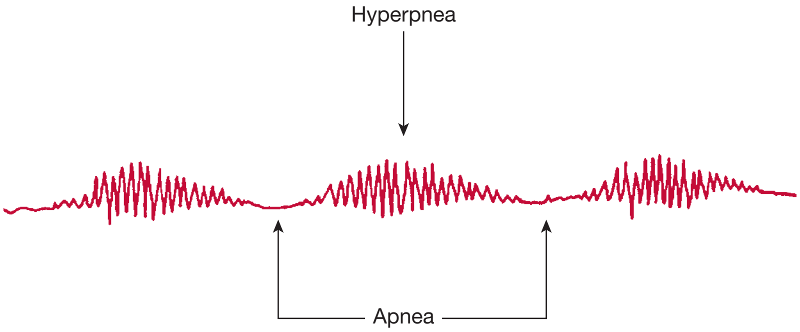

Figure 98-20 Example of Cheyne–Stokes respiration (CSR), a pattern of periodic breathing in which intervals of hyperpnea alternate with intervals of apnea. Respiration waxes and wanes in a crescendo–decrescendo pattern. Arousals during CSR tend to occur during the peak of ventilation, that is, during the hyperpneic phase rather than at the termination of the apnea. The duration of the hyperpneic phase of CSR correlates with the degree of circulatory delay.

associated with CSR, which tend to occur at the peak of ventilation, distinguish them from arousals associated with obstructive events, which occur at apnea termination. Thus, arousals during CSR provoke ventilatory overshoot and help to sustain oscillations in respiration, rather than fostering upper airway muscle activation and the resumption of airflow as occurs in obstructive apneas.[688] The cycle length in CSR generally ranges from 40 to 90 s, due in part to prolonged transit time between the lungs and chemoreceptors in the setting of reduced cardiac output and increased circulation time.[657]

The clinical presentation of patients with CSR is variable. Although some patients with heart failure and CSR complain of sleep fragmentation, daytime sleepiness, and poor nocturnal sleep, many do not.[689] The diagnosis of CSR is established by PSG demonstrating repetitive apneas in the absence of thoracic–abdominal excursion.[15] Not infrequently, a combination of obstructive and mixed apneas may be seen; central SDB events must constitute greater than 50% of total events to make the diagnosis of CSA.[688]

CSR can be treated in several ways. Aggressive pharmacologic management of heart failure, including beta blockade and angiotensin-converting enzyme inhibitors, improves heart failure status and may reduce CSA.[690,691] The use of supplemental oxygen can help to stabilize oscillations in ventilation but generally does not normalize the AHI.[692,693] Data demonstrating improved long-term outcomes with use of supplemental oxygen are lacking. However, given results from several recent trials demonstrating improvements in LV ejection fraction among patients with heart failure and CSA who received oxygen, supplemental oxygen has been recommended for this patient population.[694–697] Administering a small amount of CO_2 to patients with CSR dramatically reduces central apneas by increasing Pa_{CO_2} above the apnea threshold. This intervention has not, however, been implemented clinically due to concerns about long-term increases in Pa_{CO_2}.[698]

Although a number of initial reports demonstrated that CPAP therapy lowers AHI, reduces systolic BP, and improves LV systolic function, this treatment has proven disappointing.[676,699,700] A large, randomized trial in individuals with heart failure and CSA failed to demonstrate mortality benefit after use of CPAP for 2 years, despite improvements in the severity of CSA, nocturnal oxygenation, ejection fraction, and other physiologic measurements.[701] Furthermore, while early survival was lower among those receiving CPAP, mortality was ultimately not significantly different between the groups. Post hoc analyses demonstrated that among those individuals receiving CPAP whose CSA was reduced to less than 15 events/h, survival was improved.[702] Whether these findings represent benefit from CPAP use in this subgroup, however, or whether the reduction in AHI to less than 15 events/h identified individuals with a better overall prognosis, is unclear.

A mode of PAP therapy termed *adaptive servo-ventilation (ASV)* has been developed for use in patients with CSR and other forms of hypocapnic CSA.[703] ASV provides bilevel PAP with a fixed expiratory pressure and variable inspiratory pressure that responds to changes in the ventilatory pattern while maintaining a target ventilation based on a continuous moving window of the patient's recent average ventilation. Thus, over time, proportionate increases and decreases in inspiratory pressure occur that help to stabilize ventilation. A number of randomized trials and other studies have shown that ASV improves CSA associated with CSR due to heart failure, as well as LV ejection fraction, sleep disruption, and exercise capacity.[704–709] However, a multinational, multicenter, randomized trial of patients with symptomatic chronic heart failure with depressed LV ejection fraction (≤45%) and predominant CSA demonstrated a lack of efficacy and actually increased cardiovascular mortality among individuals assigned to ASV.[710] After assessing the available current data, the AASM has recommended the use of CPAP or oxygen for first-line treatment of CSR related to heart failure,[697] and recommended against the use of ASV to treat CHF-associated CSA in patients with low ejection fraction and moderate or severe CSA.[711]

More recently, there has been evidence supporting the use of unilateral transvenous phrenic neurostimulation in patients with central sleep apnea.[712] This novel physiologic treatment demonstrated efficacy in a multicenter, randomized, controlled trial.[712] After 6 months, improvements were noted in AHI, sleep architecture, and quality of life in CSA patients receiving phrenic neurostimulation, including those with significant comorbidities such as stage A–C heart failure, compared to those who had the device implanted at the time of randomization but not activated.[712] Once the device was approved by the FDA, all devices were activated and a pooled cohort (treatment and former control group) was followed for 36 months with similar results.[652] Fifty-two participants were followed for 5 years and were noted to have improved CSA, sleep architecture, and daytime sleepiness.[713] Importantly, phrenic nerve stimulation was well tolerated with no serious events leading to long-term harm or death.[713]

■ Idiopathic Central Sleep Apnea

An idiopathic form of CSA similar to CSR has occasionally been described in individuals with normal cardiac function. Presenting symptoms can include snoring, witnessed apneas, insomnia, and excessive sleepiness.[714–716] These individuals have an increased ventilatory response to CO_2 during sleep and wakefulness. There is no standardized treatment. While CPAP therapy has proved effective for some patients, other reported treatments have included respiratory stimulants such as acetazolamide and use of benzodiazepine and hypnotic medications to improve sleep continuity and reduce sleep state instability.[717–720]

■ Treatment-emergent Central Sleep Apnea

In recent years, the terms "treatment-emergent sleep apnea" (TECSA) or "complex sleep apnea" have been applied to the emergence of central apneas during CPAP titration for treatment of OSA.[646] The prevalence of TECSA has been estimated to be between 5% and 15% of patients undergoing CPAP titration.[646,721–724]

Individuals who manifest CPAP-emergent central apneas have been described in some studies to be more likely to be male, to be older, to have a lower BMI, and to have a history of cardiac disease compared with individuals without treatment-emergent central sleep apnea.[725]

Polysomnography in patients with TECSA may reveal recurrent central apneas occurring particularly during the lighter stages of sleep (N1 and N2), with more stable breathing during N3 and REM sleep.[726] Patients may have characteristics such as a lower arousal threshold or high ventilatory controller gain that place them at risk for ventilatory control instability.[38] Some patients report persistent sleep disruption with CPAP therapy with little symptomatic benefit.

The clinical relevance of TECSA has been vigorously debated, given evidence that CPAP-emergent central apneas may be associated primarily with CPAP initiation and are likely to resolve over time.[727,728] Among patients who were initially diagnosed with complex sleep apnea, only 20% to 25% of patients who returned for PSG after using CPAP for 1 to 3 months had persistent central apneas greater than 5/h.[721,724] Other explanations for CPAP-emergent central apneas include over- and undertitration of CPAP therapy, the presence of occult heart failure, and use of respiratory-depressant medications such as opioids and benzodiazepines.[728] Use of chronic opioid medications, which has become much more common in the past several decades, also places patients at risk for central sleep apnea events during sleep.[207,729,730]

The results of several studies that have examined the use of PAP devices for treatment of TECSA suggest that adaptive servo-ventilation appears to most effectively reduce AHI.[704,731,732] However, evidence suggests that TECSA resolves spontaneously in the majority of patients after several months of CPAP therapy.[721] Therefore, it seems reasonable to initiate a trial of CPAP therapy first and to reserve ASV for the relatively few individuals who exhibit persistent apnea, including those using opioids.

EFFECT OF SLEEP IN PATIENTS WITH PULMONARY DISORDERS

Normal sleep is associated with relative hypoventilation and hypoxemia compared to wakefulness. This may occur via a variety of mechanisms. Sleep onset has been associated with a 2- to 6-mm Hg increase in the P_{CO_2} set point for ventilation.[733,734] Hypoxic ventilatory responses can be reduced such that normal subjects may experience a decrement of up to 10 mm Hg of Pa_{O_2} during sleep; this response may be more pronounced in men compared with women.[139,735,736] Sleep is also associated with changes in respiratory mechanics, the most obvious of which are due to the posture adopted during sleep. The supine position, in particular, is associated with an additional load on inspiratory muscles due to a shifting of abdominal contents.[737] REM sleep is associated with atonia, which spares the diaphragm, but not the accessory and other muscles of respiration and can reduce functional residual capacity.[738,739] Upper airway patency is dependent on muscle activity, which can be reduced or absent in NREM versus REM sleep and by an increase in supraglottic resistance.[740]

Pulmonary disorders can deteriorate during normal sleep and especially in patients with concomitant sleep apnea. SDB is associated with exaggeration of the normal circadian changes that elicit increases in bronchial hyperresponsiveness, vagal tone, and airway inflammation, which can contribute to asthma.[741–753] The sleep disruptions and hypoxia associated with SDB can also promote insulin resistance and glucose intolerance that, coupled with daytime sleepiness and reduction in general activity, ultimately lead to weight gain.[161,324,391,510,753–755] Obesity, in turn, is a significant risk factor for asthma.[753,756–762] Furthermore, snoring or apnea is likely to worsen gastroesophageal reflux, which in turn, is known to exacerbate asthma.[763–766] Studies addressing nocturnal asthma and OSA have shown symptom improvement with CPAP use.[767–770] Given these interactions, asthmatic patients who fail to improve with optimal medical therapy or who manifest primarily nocturnal asthma should be considered for evaluation of sleep apnea, particularly if snoring is present.[753,767]

In obstructive lung diseases such as COPD, those patients who exhibit daytime hypoxemia also experience profound declines in Pa_{O_2}, especially during REM sleep.[771,772] Hypoxemia is multifactorial: Mechanisms include exaggerated changes in respiratory physiology during sleep such as reduced functional residual capacity (which decreases oxygen reserve), increased airway resistance, decreased respiratory muscle function, altered chemosensitivity, alveolar hypoventilation, and ventilation–perfusion mismatch.[773] The coexistence of COPD and OSA is relatively frequent because both disorders are so common.[774,775] In this so-called overlap syndrome, patients are at increased risk of pulmonary hypertension and respiratory failure related to progressive nocturnal hypoxemia.[716,775–777] Patients are also at increased risk of death and hospitalization due to COPD exacerbation.[778]

While oxygen is the therapy of choice in COPD patients with daytime hypoxia, its chronic use in patients with isolated nocturnal hypoxia without SDB is without clear benefit.[737,779–783] Oxygen therapy is unlikely to be sufficient in patients who suffer overlap syndrome. In patients with COPD and chronic hypercapnia, the use of high intensity nocturnal noninvasive positive pressure ventilation has been shown to reduce mortality,[784] after a series of studies suggesting noninvasive ventilation was unlikely to be of added benefit.[785–787] Patients with overlap syndrome who are treated with CPAP have also been noted to have improved survival and decreased hospitalizations due to fewer COPD exacerbations.[778] Given this observation, screening of COPD patients for clinical features indicative of coexistent OSA is warranted.[778]

It is important to recognize that a wide variety of other lung diseases, including both parenchymal lung disease and neuromuscular disease, can place patients at risk for hypoxemia during sleep. This is related to operating on the steep segment of the sigmoid-shaped oxygen dissociation curve while awake.[783] As with patients with COPD, the benefit of oxygen therapy during sleep in patients with isolated nocturnal oxygen desaturations is not clearly established; clinical judgment should be exercised before instituting such therapy, and reassessment is advised.[783] Furthermore, it is likely that OSA is common in other types of lung diseases such as idiopathic pulmonary fibrosis and sickle cell disease.[788,789] The role of CPAP has yet to be defined in these other disorders.

CONCLUSION

The past several decades have brought major advances in our understanding of normal and disordered breathing during sleep. Results from epidemiologic studies from around the world continue to illuminate our understanding of the consequences of OSA, which extend far beyond excessive daytime sleepiness to include cardiometabolic morbidity and increased mortality. Advances in basic and translational research reveal that the effects of obesity on OSA risk occur not only via anatomic and functional effects but also through effects on ventilation and neuromuscular control of the upper airway. There is likely a specific fat distribution that is important, that is, tongue fat. Evidence that effective treatment of OSA can reduce morbidity and mortality continues to accumulate. And as we learn more about the genotypic and phenotypic expression of sleep apnea, we are likely to be able to better tailor individualized therapies for patients. There is developing evidence that OSA is a heterogeneous disorder with respect to symptoms and physiologic consequences.

These advances are occurring against a backdrop of greater demand for sleep medicine services and reforms in health care that have generated growing pressure to streamline the diagnosis and management of sleep apnea patients with an emphasis on out-of-laboratory, portable testing. In response, new treatments for SDB continue to be developed and new technologies are helping providers to better understand and motivate adherence to PAP therapy. As algorithms for effective management within these systemic constraints are developed and implemented, the intensifying focus within healthcare on patient-centered, outcomes-based care demands that these principles be incorporated into successful models of care for sleep disorders. Meeting this challenge is imperative to our ability to provide optimal patient care and to make continued advances in our understanding of sleep-disordered breathing.

CHAPTER 99

Sleep-related Hypoventilation Syndromes

Jorge I. Mora
Richard J. Schwab

INTRODUCTION

Sleep induces profound changes on the respiratory system (Chapter 100), especially in patients with underlying cardiopulmonary or neuromuscular disorders. Sleep-related hypoventilation syndromes have in common an abnormal increase in partial pressure of carbon dioxide (Pa_{CO_2}) and/or a decrease in Pa_{O_2} during sleep. A rather arbitrary threshold was chosen aiming to standardize definitions and facilitate research; in 1999 the American Academy of Sleep Medicine (AASM) included an arterial Pa_{CO_2} >45 mm Hg during wakefulness and a greater than 10 mm Hg increase in Pa_{CO_2} during sleep from awake supine values in the definition of sleep hypoventilation syndromes.[1] Similarly, the International Classification of Sleep Disorders (ICSD-3) incorporated a Pa_{CO_2} during sleep greater than 45 mm Hg or, more vaguely than the AASM definition, a disproportionate increase relative to levels during wakefulness in the diagnostic criteria for sleep-related hypoxemia/hypoventilation syndromes.[2] The AASM Sleep Apnea Definitions Task Force revised scoring of sleep hypoventilation in 2012 to include a Pa_{CO_2} increase >55 mm Hg for ≥10 min or a ≥10-mm Hg increase in Pa_{CO_2} during sleep in comparison to awake supine values to a value exceeding 50 mm Hg for ≥10 minutes.[3] These definitions are clearly subjective. While based on data that normal individuals rarely have a Pa_{CO_2} >55 mm Hg during sleep, the precise Pa_{CO_2} demarcating the transition from physiologic hypercapnia to pathologic hypoventilation remains unclear. The duration of 10 min chosen by the AASM Task Force was arbitrary and based on consensus with a lack of normative data on the amount of total sleep time at different values of Pa_{CO_2} in sleeping adults.[3] The measurement of fluctuations in Pa_{CO_2} during sleep is rather impractical and probably unattainable outside of a research setting. The determination of surrogate variables, such as end-tidal CO_2 ($ETCO_2$) or transcutaneous CO_2 ($PtcCO_2$) are more suitable for routine medical practice. However, these measurement methods are susceptible to imprecision when correlated with Pa_{CO_2} either due to sensor drifting ($PtcCO_2$) or due to altered underlying ventilatory physiology (underestimation of Pa_{CO_2} by $ETCO_2$ in the setting of increased dead-space ventilation), or because of technical inaccuracies.

Sleep is associated with stage-specific changes in ventilation covered in Chapter 100. Loss of the wakefulness drive to breathe, altered ventilatory response to hypoxia and hypercapnia, and increased upper airway resistance result in a decrease in ventilation in both non–rapid eye movement (NREM) and rapid eye movement (REM) sleep when compared with wakefulness. Consequently, there is a small normal physiologic increase in the Pa_{CO_2}, usually no larger than 6 mm Hg during sleep.

The small decrease in ventilation and increase in Pa_{CO_2} during sleep is usually of little clinical consequence in normal individuals. However, in patients with respiratory muscle weakness, altered respiratory mechanics, impaired gas exchange in pulmonary disease, and/or abnormal ventilatory drive, sleep is a vulnerable time. Nocturnal hypoventilation often precedes chronic diurnal hypoventilation and hypercarbia; a high index of clinical suspicion is necessary as the extent to which sleep can elicit and drive the clinical progression of chronic hypoventilation is often underappreciated. The benefit of early initiation of nocturnal ventilatory support in subclinical diurnal hypoventilation (daytime eucarbia in presence of sleep-related alveolar hypoventilation and episodic hypercarbia) is intuitively attractive, but the evidence supporting this intervention is currently lacking. What is clear is that nocturnal ventilatory support during sleep in clinically overt hypoventilatory syndromes (i.e., chronic daytime hypercarbia) is clinically beneficial. In this chapter we review the common causes of sleep-related hypoventilation.

CAUSES OF SLEEP-RELATED HYPOVENTILATION

The Pa_{CO_2} is determined by CO_2 production divided by alveolar ventilation—total minute ventilation or MV (total tidal volume times respiratory rate) minus dead-space minute ventilation or MVds (dead-space tidal volume times respiratory rate).

$$Pa_{CO_2} = CO_2 \text{ production}/(MV - MVds)$$

Hypercapnia results when alveolar ventilation is insufficient to meet metabolic needs and is caused by a decrease in minute ventilation, an increase in dead space ventilation, or, rarely, an increase in CO_2 production. The causes of sleep-related hypoventilation can be thought of as disorders of ventilatory drive, that is, "won't breathe," or disorders of respiratory mechanics and/or impaired gas exchange, that is, "can't breathe" (Table 99-1).[4] The ICSD-3 classified sleep-related hypoventilation/hypoxemic syndromes by etiology (Table 99-2).[2]

DISORDERS OF VENTILATORY CONTROL

Disorders of ventilatory drive may result in central apnea and nocturnal hypoventilation (hypercarbic central apnea). These disorders can be primary, including congenital central hypoventilation syndrome (CCHS) and primary idiopathic alveolar hypoventilation, where no other cause for central hypoventilation is found. Alternatively, these disorders can be acquired, usually following neurologic disorders that affect the brain stem and spinal cord, or in acute and chronic opiate use.

TABLE 99-1 The 2005 International Classification of Sleep Disorders

ISCD-2 classification of sleep-related hypoventilation/hypoxemic syndrome

- Sleep-related hypoventilation/hypoxemic syndromes
  - Sleep-related nonobstructive alveolar hypoventilation, idiopathic
  - Congenital central alveolar hypoventilation syndrome
- Sleep-related hypoventilation/hypoxemia due to medical condition
  - Sleep-related hypoventilation/hypoxemia due to pulmonary parenchymal or vascular pathology
  - Sleep-related hypoventilation/hypoxemia due to lower airway obstruction
  - Sleep-related hypoventilation/hypoxemia due to neuromuscular and chest wall disorders

TABLE 99-2 Sleep-related Respiratory Abnormalities

Main Category	Subcategory	ICD-10-CM
Obstructive sleep apnea	Obstructive sleep apnea in adults	G47.33
	Obstructive sleep apnea in children	G47.33
Central sleep apnea	Central sleep apnea with Cheyne–Stokes breathing	R06.3
	Central sleep apnea due to a medical cause without Cheyne–Stokes breathing	G47.37
	Central sleep apnea due to high-altitude periodic breathing	G47.32
	Central sleep apnea due to drugs or substances	G47.39
	Primary central sleep apnea	G47.31
	Primary central sleep apnea in children	P28.3
	Primary central sleep apnea in premature infants	P28.4
	Central sleep apnea due to therapy	G47.39
Sleep-related hypoventilation	Obesity hypoventilation syndrome	E66.2
	Congenital central alveolar hypoventilation syndrome	G47.35
	Late-onset central hypoventilation with hypothalamic dysfunction	G47.36
	Idiopathic central alveolar hypoventilation	G47.34
	Sleep-related hypoventilation due to drugs or substances	G47.36
	Sleep-related hypoventilation due to a medical cause	G47.36
Sleep-related hypoxia	Sleep-related hypoxia	G47.36

■ Congenital Central Alveolar Hypoventilation Syndrome

Congenital central hypoventilation syndrome (CCHS), initially referred to as Ondine's curse, is a rare cause of central hypoventilation first described in 1970 by Mellins et al.[5] In 2003, the *PHOX2B* gene was identified as the disease-defining gene for CCHS. More than 1000 cases have been reported worldwide. The estimated incidence is 1 in 150,000–200,000 live births in France and Japan.[6] CCHS is characterized by hypoventilation and diffuse autonomic nervous system dysregulation (ANSD). Studies suggest abnormal brainstem integration of chemoreceptor afferent pathways for ventilation with demonstration of some, albeit blunted, physiologic response of both central and peripheral chemoreceptors. Abnormal central integration of chemoreceptor afferents is also thought to be responsible for the autonomic nervous system dysfunction seen in CCHS. Traditionally considered a disorder of infants and children, with advancements in knowledge and treatment, patients are now often surviving into adulthood. This lifelong disorder is rare.

CCHS is caused by a mutation in the paired-like homeobox 2B (*PHOX2B*) gene.[7,8] The *PHOX2B* gene on chromosome 4p12 encodes for a transcription factor that plays a role in the development of the autonomic nervous system and regulation of neural crest cell migration. This is shown by studies in mice in which the *PHOX2B* gene was knocked out. Such mice have abnormal development of the respiratory control system and have no ventilatory response to CO_2.[9] Approximately 90% of *PHOX2B* mutations involve polyalanine repeat expansion mutations (PARMs) producing genotypes (number of repeats) of 20/24 to 20/33, whereas the normal genotype is 20/20. The remaining 10% of cases are heterozygous for nonpolyalanine repeat mutations (NPARMs) and include missense, nonsense, or frameshift mutations. Most expansion mutations occur de novo, but in 5% to 10% of cases parents are mosaic for the *PHOX2B* mutation, with a 50% chance of transmitting the mutation.[10]

CCHS is a clinically heterogeneous disorder. Studies have demonstrated a relationship between the *PHOX2B* genotype and CCHS phenotype. A spectrum of hypoventilation severity is seen; patients with 20/27 to 20/33 genotype typically require 24-h continuous ventilatory support.[11] The syndrome is typically diagnosed in newborns with episodes of cyanosis and apnea usually requiring mechanical ventilation. After maturation of the respiratory and central nervous systems, many patients with CCHS eventually breathe adequately while awake (wakefulness stimulus to breathe) but show hypoventilation during sleep. CCHS does not resolve spontaneously. Hypoventilation in CCHS is most apparent in NREM compared to REM sleep. This is unique from other sleep-related breathing disorders and is thought to be due to an intrinsic REM-related ventilatory drive,[12] whereas during NREM sleep breathing is critically dependent on the metabolic/automatic control of breathing.

Children with CCHS lack perception of dyspnea and may not manifest signs of respiratory distress; they are unable to augment ventilation when faced with a respiratory challenge like an infection or anesthesia and, therefore, these patients may develop sudden decompensated respiratory failure. When unrecognized, children with CCHS present with complications of chronic hypoventilation, including pulmonary hypertension, cor pulmonale, seizures, or developmental delay. Patients can present outside the newborn period with late-onset central hypoventilation syndrome (LO-CCHS) (reported as late as 35 years of age) in individuals with only a minor increase in polyalanine repeats.[13] Careful review of their medical history typically reveals signs and symptoms compatible with hypoventilation and autonomic dysregulation from the newborn period. This may reflect the variable penetrance of *PHOX2B* mutations and should be distinguished from rapid-onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation (ROHHAD) which is not associated with *PHOX2B* mutations. Patients with this syndrome typically present after the age of 2 years with hyperphagic obesity followed by hypothalamic and autonomic dysregulation, central hypoventilation, and behavioral changes. The syndrome is now considered distinct from CCHS.[10,14]

Autonomic nervous system dysfunction (ANSD) and disorders of neural crest origin are common in CCHS. Hirschsprung disease (a congenital malformation of the enteric nervous system) has been reported in approximately 16% of patients with CCHS and is often of greater severity than in the general population with Hirschsprung disease. Neural crest tumors including neuroblastoma or ganglioneuroma have been described in 5% of patients with CCHS.[15,16] Other symptoms of ANSD described in CCHS patients include diminished pupillary light response, temperature instability, sporadic profuse sweating, altered perception of discomfort and anxiety, and esophageal dysmotility. Cardiac arrhythmias, including decreased beat-to-beat heart rate variability, reduced respiratory sinus arrhythmia, and asystole, have been observed.[10,17] Children with CCHS may have a characteristic box-shaped facies that is shorter and flatter (Fig. 99-1).[18] *PHOX2B* genotype–CCHS phenotype relationships have been demonstrated for the more severe CCHS phenotypes that manifest Hirschsprung disease and tumors of neural crest origin; Hirschsprung disease is most prevalent in patients with NPARM and PARM with more than 20/27

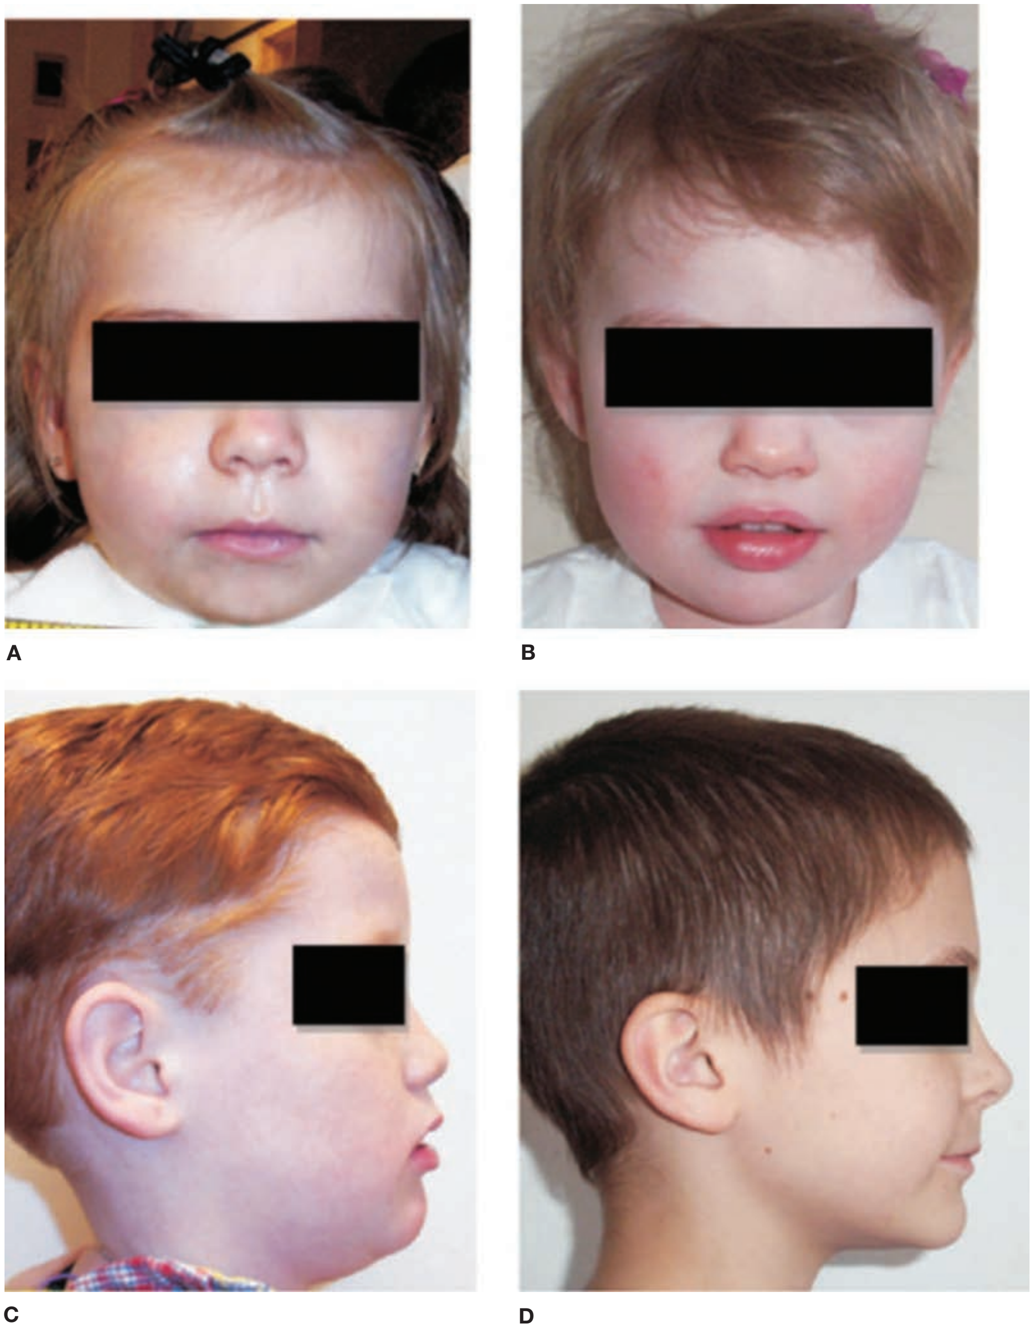

Figure 99-1 Photographs of representative congenital central hypoventilation syndrome (**A** and **C**) and control (**B** and **D**) subjects showing representative box-shaped facies of CCHS with decreases in the slope of the forehead, upper face height, upper facial inclination, nasolabial angle, upper and lower lip heights, and inferior inflection of the lateral vermillion border of the upper lip. *(Reproduced with permission from Todd ES, Weinberg SM, Berry-Kravis EM, et al. Facial phenotype in children and young adults with PHOX2B-determined congenital central hypoventilation syndrome: quantitative pattern of dysmorphology. Pediatr Res. 2006;59(1):39–45.)*

mutations.[19] Neural crest tumors have been described in 50% of NPARMs compared with 1% in controls.[10]

Diagnosis of CCHS relies on genetic testing after excluding other causes of central hypoventilation including pulmonary, neurologic, and metabolic etiologies. Genetic testing with the PHOX2B Screening Test will identify mutations in 95% of cases. If the PHOX2B Screening Test is negative but there remains a high clinical suspicion, direct sequencing of the gene can be performed to detect NPARM mutations.

Alveolar hypoventilation is the hallmark of CCHS. The severity of respiratory failure and the need for ventilatory support can be anticipated by a patient's genotype. Polysomnography (PSG) coupled with continuous CO_2 monitoring, either $ETCO_2$ or $PtcCO_2$, permits assessing ventilatory patterns and specific requirements in all stages of sleep. Further diagnostic studies are guided by the clinical evaluation and include, but are not limited to, screening for other autonomic dysfunction, including Hirschsprung with a barium enema or manometry, cardiac arrhythmias with 72-h Holter monitoring, neural crest tumors with serial chest and abdominal imaging, pupillary function with a comprehensive ophthalmologic examination, and neurocognitive testing.

Nocturnal ventilatory support can be provided by various modalities, including invasive positive-pressure ventilation via tracheostomy or noninvasive positive-pressure ventilation (NIPPV) via a nasal or face mask, ideally with a backup power source (battery) and alarm features. Volume-cycled or pressure-cycled ventilation can be used depending on patient's tolerance. The mode of ventilatory support should be guided by the needs of the patient. In infants and younger children, positive-pressure ventilation via tracheostomy is preferred.

Modern home ventilators and newer ventilatory algorithms (e.g., iVAPS or "intelligent" volume assured pressure support) make NIPPV a palatable and safe option when only nocturnal ventilatory support is required. These ventilators guarantee the delivery of a steady minute ventilation during sleep. In absence of concomitant noncentral hypoventilation, diaphragmatic pacing remains a feasible treatment option—more so in patients who require 24-h respiratory support. Monopolar electrodes are implanted on both phrenic nerves along with receivers in the abdomen or chest, which convert energy received via antennas into electrical currents that are then conducted by the phrenic nerves and result in diaphragmatic contraction. Note that novel devices for diaphragmatic pacing, such as remedē®, are not suited for CCHS. Respiratory stimulants, such as medroxyprogesterone, have not been shown to improve ventilatory drive in CCHS.[20]

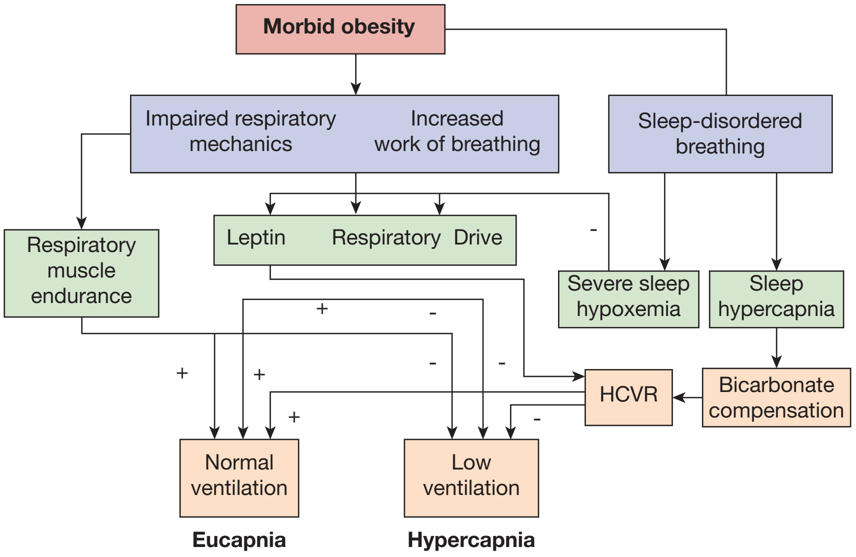

Figure 99-2 Interaction of the various pathophysiologic mechanisms implicated in the development of hypercapnia in the obesity hypoventilation syndrome. (+), positive influence on maintaining ventilation if normal or increased; (–), negative influence on maintaining ventilation if reduced or blunted; HCVR, hypercapnic ventilator response. *(Reproduced with permission from Piper AJ, Grunstein RR. Big breathing: the complex interaction of obesity, hypoventilation, weight loss, and respiratory function. J Appl Physiol. 2010;108(1):199–205.)*

With early diagnosis, close monitoring, and support, children with CCHS can be expected to function well in society and have a good quality of life, but mortality rates of 8% to 38% have been reported.[15] Genetic counseling is essential for individuals diagnosed with CCHS. *PHOX2B* gene mutation in CCHS has an autosomal pattern of inheritance with variable penetrance.[21] This results in a rather broad phenotypic spectrum, and despite most cases presenting de novo, asymptomatic parents of the affected child should be tested. Genetic counseling is imperative for individuals with CCHS and their families, as there is a 50% chance of recurrence with each child.[22]

■ Obesity Hypoventilation Syndrome

The obesity hypoventilation syndrome (OHS) is defined by the presence of obesity (body mass index [BMI] $\geq$30 kg/m^2), chronic alveolar hypoventilation with daytime hypercapnia (awake Pa_{CO_2} $\geq$45 mm Hg), and sleep-related breathing disorder in the absence of any other causes of hypoventilation. While first described in ancient Greek literature, it was not until the 1950s following case descriptions by Auchincloss et al.[23] and, later, Bickelmann et al.[24] that the syndrome gained attention and the term *Pickwickian syndrome*, from the character of Joe in *The Posthumous Papers of the Pickwick Club* by Charles Dickens, emerged.[25]

The risk of OHS increases as BMI increases. In the United States by 2018, approximately 42% of the population was obese.[26] As prevalence of obesity and in particular super obesity (BMI $\geq$50 kg/m^2) increases exponentially, OHS has become a leading cause of sleep-related hypoventilation. A prevalence of 10% to 20% has been reported in obese patients with obstructive sleep apnea (OSA), almost 50% in hospitalized patients with a BMI $\geq$50 kg/m^2, while a conservative prevalence of 0.3% has been estimated in the general U.S. adult population.[27–29] Multiple studies have reported a prevalence of OHS between 8% and 20% in obese patients referred to sleep centers for evaluation of OSA.[30–32]

Pathophysiology

The precise mechanism by which obesity leads to hypoventilation remains incompletely understood. There is likely a complex interaction[33] between (1) abnormal respiratory system mechanics and increased work of breathing due to obesity (reduced chest wall and respiratory system compliance, increased airway resistance, expiratory flow limitation, intrinsic positive end-expiratory pressure, reduced respiratory muscle efficiency); (2) sleep-related breathing disorder; and (3) blunted central hypercapnic and hypoxic ventilatory drive, including central hypothalamic "resistance" to leptin (a protein produced mainly by adipose tissue that stimulates ventilation) (Fig. 99-2).[28]

In approximately 90% of OHS patients there is an associated sleep-related breathing disorder, that is, Obstructive Sleep Apnea (OSA); nearly 70% have severe OSA (Apnea Hypopnea Index [AHI] >30 events/h).[34] In the remaining 10% the sleep-related breathing disorder is nonobstructive sleep hypoventilation characterized by sustained hypoxia and an increase in Pa_{CO_2} by 10 mm Hg above wakefulness in the absence of significant obstructive apneas or hypopneas. More recently, OHS has been suggested to result from an inadequate compensatory ventilatory response to offload the CO_2 that accumulates during apneic and hypopneic events in sleep.[35] In addition, if the bicarbonate retained by the kidneys to buffer this transient decrease in pH is slowly eliminated, there is further blunting of the ventilatory responsive to CO_2, causing progressive hypercapnia (Fig. 99-3).[36]

Clinical Presentation

OHS is associated with increased morbidity and mortality, higher rates of hospitalization and ICU admissions, increased healthcare utilization, and reduced quality of life.[27–29,37] Timely diagnosis is essential, given higher rates of systemic hypertension, angina, congestive heart failure, and cor pulmonale that are reported in OHS compared to eucapnic obese individuals.[28,37] Yet, despite the clinical consequences of OHS the diagnosis is often overlooked and a higher index of clinical suspicion is required.[29]

Typical symptoms of OSA (Chapter 98) are commonly reported by OHS patients, but additional symptoms of hypercapnia including morning headaches, and excessive daytime sleepiness despite adequate control of OSA, may be present. Dyspnea is more frequently reported than in eucapnic OSA patients. Pulmonary hypertension,

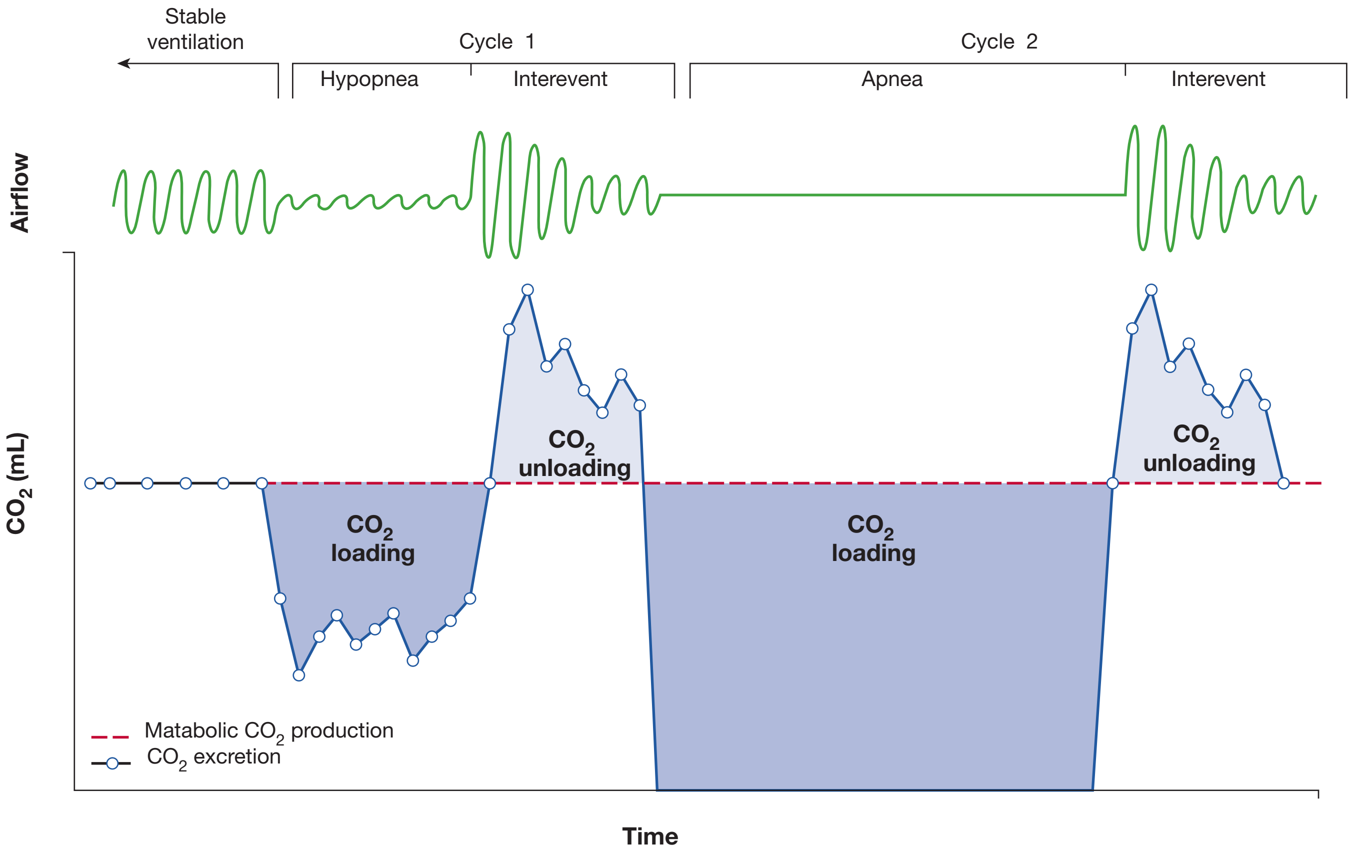

Figure 99-3 Schema depicting a proposed inadequate compensatory ventilatory response to CO_2 loading during obstructive respiratory events in the obesity hypoventilation syndrome. The dark-shaded areas depict CO_2 loading due to reduced CO_2 excretion during respiratory events, while the light-shaded areas depict CO_2 unloading due to compensatory hyperventilation between respiratory events. *(Reproduced with permission from Berger KI, Goldring RM, Rapoport DM. Obesity hypoventilation syndrome. Semin Respir Crit Care Med. 2009;30(3):253–261.)*

cor pulmonale, and polycythemia are also more common in patients with OHS compared with patients with OSA alone. It is not infrequent for patients with OHS to initially present with decompensated acute on chronic hypercapnic respiratory failure requiring the ICU and ventilatory support.

Physical examination in these patients may reveal facial plethora, injected sclera, a prominent pulmonic component of the second heart sound, and signs of right heart failure including lower extremity edema in addition to signs suggestive of OSA. Compared with eucapnic OSA patients, OHS patients commonly have awake hypoxemia typically with a Pa_{O_2} less than 70 mm Hg. Awake hypoxemia is uncommon in eucapnic OSA patients, and a pulse oximetry recording of <94% in patients with OSA should prompt consideration of an arterial blood gas (ABG) measurement.[28]

Diagnostic Approach

The diagnosis of OHS relies on demonstration of awake hypercapnia, and an arterial blood gas on room air is necessary. Chronic hypercapnia may be suggested by an elevated serum bicarbonate, and a serum bicarbonate of 27 mEq/L or greater has been shown to be highly sensitive (92%) but not specific (50%) for chronic hypercapnia.[28,38] Chronic kidney disease and the use of loop diuretics, both common in this population with multiple comorbidities, may affect bicarbonate homeostasis, limiting the role of assessment of serum bicarbonate as a screening tool. The American Thoracic Society position statement on OHS suggests that obese patients with sleep disordered breathing (SDB) who are strongly suspected of having OHS should undergo determination of Pa_{CO_2}, rather than having clinicians rely on serum bicarbonate or Sp_{O_2} to diagnose OHS.[39]

Typically, patients manifest a >10 mm Hg increase in their Pa_{CO_2} during sleep. The presence of deep nonobstructive desaturations or lack of Sp_{O_2} recovery after an obstructive event during polysomnography (PSG) suggest underlying hypoventilation. The use of $ETCO_2$ or $PtcCO_2$ monitoring during PSG should be considered in all obese patients undergoing sleep testing, even in absence of diurnal hypercarbia, as episodic hypercarbia during REM is commonly seen in these patients.

OHS is a diagnosis of exclusion. Other causes of chronic hypoventilation including significant pulmonary disease, chest wall disorders, neuromuscular disease, severe hypothyroidism, and other central hypoventilation syndromes must be excluded. However, it is likely that the pathophysiologic mechanisms underlying OHS coexist with many of these disorders, for example, COPD; they are synergistic. Further diagnostic testing should be guided by the clinical history and physical examination, but should also include pulmonary function testing, lung imaging, electrocardiography, thyroid function testing, and a sleep study, in which a characteristic pattern is often seen, including increased sleep time with Spo_2 <90%, as demonstrated in Fig. 99-4.[28,40,41]

Treatment

Continuous positive airway pressure (CPAP) and nocturnal noninvasive positive pressure ventilation (NIPPV) are currently the mainstay of treatment for OHS. Applying positive airway pressure (PAP) has been shown to improve morbidity and mortality, hypercapnia and hypoxemia, symptoms, pulmonary hypertension, and quality of life.[27,41–45] Despite the widespread adoption of PAP, the best modality remains unknown as the majority of studies are observational,

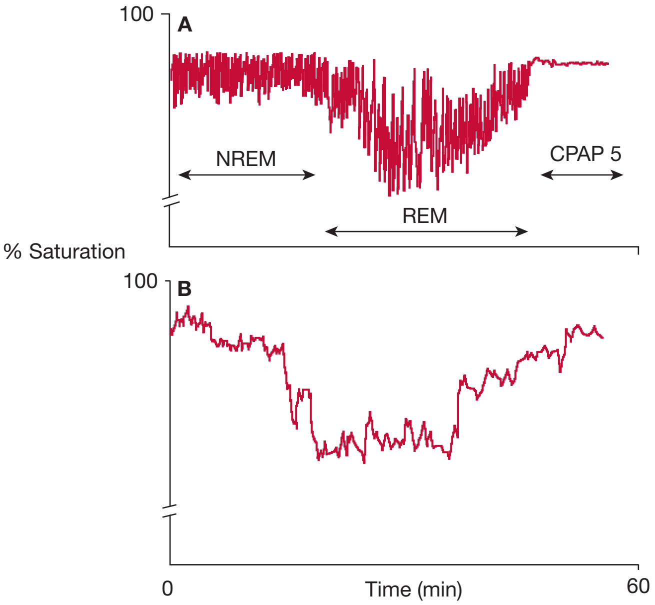

Figure 99-4 **A.** Nocturnal oximetry in a patient with severe obstructive sleep apnea demonstrating recurrent desaturations in nonrapid eye movement (NREM) and rapid eye movement (REM) sleep. Each apneic event results in an oxyhemoglobin desaturation that improves as the apnea is terminated. The degree of desaturation is greater in REM sleep and resolves when continuous positive airway pressure (CPAP) of 5 cm H_2O is applied. **B.** In contrast to **A**, this nocturnal oximetry demonstrates prolonged desaturation in a patient with obesity hypoventilation syndrome (OHS). The desaturation corresponds to periods of prolonged hypoventilation. Although not diagnostic, this pattern is highly suggestive of OHS.

rather than randomized controlled trials, and inclusion criteria in studies are heterogeneous. Improvements in awake respiratory failure, symptoms, and quality of life are similar in OHS patients treated with either CPAP or NIPPV.[39]

CPAP relieves upper airway obstruction effectively treating OSA. Although it does not increase alveolar ventilation, it can improve wake hypercarbia by means of unloading the CO_2 that builds up during repetitive episodes of flow cessation during sleep. Since OSA is present in more than 90% of OHS patients, it is not surprising that CPAP alone has been shown to be effective in treating of the 60% to 80% of patients with OHS.[38,41,46] CPAP also improves sleep quality as measured by Functional Outcome of Sleep Questionnaire and microarousal index, significantly improves daytime sleepiness, and may reduce short-term hospitalization rates without any apparent effect on long-term readmissions.[39] This seems particularly to be the case in the OHS phenotype with higher apnea-hypopnea index (AHI), that is, moderate and severe OSA. Patients of this type seem to respond better to CPAP only, and this should be tried when patients are clinically stable in the outpatient setting. Since it is not clear what features separate responders to CPAP only from nonresponders, CO_2 should be closely monitored early in therapy. A sleep laboratory titration is useful to determine if supplemental O_2 is necessary, in addition to CPAP. The readily availability of $PtcCO_2$ monitoring (in both inpatient and outpatient settings) has made serial in-lab ABG monitoring unnecessary to define adequate ventilation parameters or to evaluate the efficacy of CPAP.[47]

Early initiation of NIPPV in this group is still a common practice, as they are commonly labeled as "CPAP failure" when polysomnography PAP titration shows they unable to sustain adequate saturations on CPAP. However, there are data to suggest that the majority of patients with stable OHS may be transitioned from NIPPV to CPAP without worsening of gas exchange.[48]

The variable response to CPAP requires close monitoring to ensure that gas exchange improvement occurs and is sustained. Should hypercapnia persist, as it does in 20% to 50% of OHS patients on CPAP,[28] these patients should be transitioned to NIPPV. The percentage of failure of CPAP can be decreased by bypassing use of CPAP in those patients with low AHI, as this phenotype is unlikely to respond to CPAP. Transition to NIPPV using either bilevel PAP or volume assured pressure support (VAPS) is indicated in the low-AHI (mild OSA)/OHS phenotype and in CPAP nonresponders after 2 months of adherent therapy. VAPS aims to maintain a target tidal volume by means of an algorithm estimating the patient's tidal volume over several breaths and adjusting pressure support (IPAP-minus EPAP) to achieve that goal. For example, if patient effort and tidal volume decreases, as it occurs during REM sleep, VAPS automatically increases pressure support to maintain the target tidal volume. Successful application of VAPS in OHS has been described, but few studies have compared it to more conventional bilevel PAP modes.[49] Given the broad availability of the latter, it should be considered as a treatment option for OHS.

Independently of whcih device or ventilatory algorithm is used for treatment, it is important to understand the ventilatory mechanics behind OHS. The diaphragm is displaced rostrally by the abdominal organs and excessive intra-abdominal fat, which results in a geometric disruption of the diaphragmatic muscle fibers, making its contraction less efficient and leading to basilar atelectasis, V/Q mismatch, and hypoxemia. Ventilation also is impaired, more so in supine REM sleep when the effects of obesity on diaphragmatic function are more prominent. Additionally, the perithoracic accumulation of adipose tissue further decreases the respiratory system compliance. Atelectasis and decreased compliance mandate use of rather prolonged inspiratory times (Ti) when applying ventilatory support, as any level of PS must be exerted for a longer time in a way that the generated tidal volume (Vt) is delivered homogenously across the lungs allowing "recruitment" of atelectatic areas while avoiding excessive inflation of non-atelectatic areas (volutrauma), all of which translates to improved V/Q matching, oxygenation, and ventilation.

No standard guidelines currently exist for bilevel PAP titration in OHS. Frequently the expiratory positive airway pressure (EPAP) is increased until inspiratory flow limitation is eliminated, followed by the addition of inspiratory positive airway pressure (IPAP) to further improve alveolar ventilation. Typically, an EPAP of 6 to 10 cm H_2O, an IPAP of 16 to 20 cm H_2O, and a difference between IPAP and EPAP ADS: (or Pressure Support) of at least 8 to 10 cm H_2O is required.[27,41,50] The precise role of using a backup rate usually set at 2 breaths/min below the wake resting respiratory rate is unknown but should be used given the ventilatory control abnormalities in these patients. If we extrapolate data from NIPPV in neuromuscular disease, it is likely that "matching" patient's respiratory rate (i.e., minimizing the number of patient-triggered breaths) provides respiratory muscle rest and may translate in improved diurnal ventilatory performance; the evidence for this in OHS is, however, lacking.

In up to half of OHS patients, supplemental oxygen is needed in addition to PAP therapy to keep Spo_2 >90%, although the need for supplemental oxygen may be reduced with continued PAP usage.[47] Oxygen therapy alone, however, is inappropriate for OHS and may prolong apnea and worsen hypercapnia.[39] Oxygen should be given only in conjunction with NIPPV.

Medical weight loss should be encouraged in all patients, but this is often difficult to achieve and maintain. Strategies include exercise, diet, behavioral interventions, pharmacotherapy, or more often, a combination of them with variable and often discouraging results.

Sustained weight loss is not frequently achieved.[51] Newer drugs such as semaglutide are promising. Semaglutide, a glucagon-like peptide 1 (GLP-1) analogue, approved as a weekly subcutaneous dose for the treatment of type 2 diabetes in adults, was associated with sustained, clinically relevant reduction in body weight (14.9%) when combined with lifestyle changes.[52]

Bariatric surgery is an effective approach to achieving sustained weight loss and should be considered in all patients with OHS. Hypercapnia can improve following bariatric surgery. A recent meta-analysis of 342 patients found that 62% of patients had residual OSA with a mean residual AHI of 16 events per hour following maximum weight loss after bariatric surgery.[53] Close clinical monitoring and a repeat sleep study are indicated following this type of surgery. Worsening hypercapnia was reported by Sugerman et al.[54] 1 to 5 years following bariatric surgery despite only a small increase in BMI, thought to be due to recurrence of a sleep-related breathing disorder. While bariatric surgery should be considered in all OHS patients, it is important to recognize that the surgery is associated with postoperative risks with a reported perioperative mortality between 0.5% to 1.5%[55,56]—hence the importance of perioperative use of NIPPV, close physiologic monitoring (Sp_{O_2} and $PtcCO_2$/$ETCO_2$), and avoidance of opioids and hypnotics.

Tracheostomy was available long before NIPPV, but there are very few large studies evaluating long-term outcomes with this therapy. A tracheostomy bypasses the upper airway and has been shown to improve OSA, but correction of daytime hypercapnia is neither universal nor complete and ongoing monitoring is necessary.[57,58] Tracheostomy is now generally reserved for those who have failed all other NIPPV modalities, which is becoming increasingly uncommon. In addition, tracheostomy is often challenging in this population given the excessive neck adipose tissue in most patients with OHS. If a tracheostomy is performed, ventilation through the trachea may still be necessary to increase minute ventilation during sleep, as OSA is effectively "bypassed" but the overall ventilatory defect persists.

Finally, while there has been interest in the use of various pharmacologic respiratory stimulants including medroxyprogesterone and acetazolamide, a carbonic anhydrase inhibitor that induces metabolic acidosis thereby increasing minute ventilation, studies are few and have small sample sizes.[27] These medications should not be used in patients with OHS because of frequent side effects and a lack of demonstrated long-term benefits.

SLEEP-RELATED HYPOVENTILATION IN PULMONARY DISORDERS

Sleep-related hypoventilation occurring in chronic obstructive pulmonary disease and in the so-called overlap syndrome (i.e., chronic obstructive pulmonary disease coexistent with OSA) are discussed below.

■ Chronic Obstructive Pulmonary Disease

Patients with chronic obstructive pulmonary disease (COPD) are particularly susceptible to nocturnal hypoventilation, especially during REM sleep (Fig. 99-5).[59] Becker et al.[60] demonstrated an approximate 16% decrease in ventilation from wakefulness to NREM sleep and an almost 32% decrease during REM compared with wakefulness in patients with COPD. The greater fall in minute ventilation in patients with COPD during sleep is largely due to a decrease in tidal volume. Patients with COPD are often hyperinflated reducing diaphragmatic efficiency, which results in increased reliance on use of accessory and intercostal muscles. During REM sleep there is muscle atonia with loss of this accessory muscle contribution such that ventilation is further reduced. Hypoventilation is further augmented by a decreased ventilatory responsiveness to CO_2 during sleep. Nocturnal hypoventilation in addition to underlying O_2 diffusion defect, result in nocturnal oxygen desaturation.

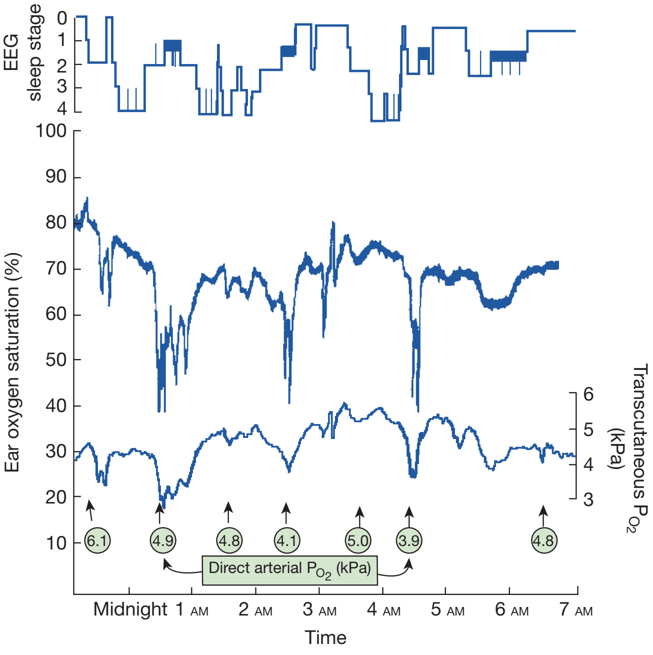

Figure 99-5 EEG sleep stage (*closed bars*, rapid eye movement [REM] sleep), ear oxygen saturation, and transcutaneous P_{O_2} in a "blue bloater" during sleep on room air depicting susceptibility to nocturnal hypoventilation, particularly during REM sleep. 1 kPa = 7.501 Torr. *(Reproduced with permission from Flenley DC. Sleep in chronic obstructive lung disease. Clin Chest Med. 1985;6(4):651–661.)*

Nocturnal oxygen desaturation is a marker of increased mortality in COPD patients.[59,61] The oxygen desaturation nadir during sleep in patients with COPD has been shown to be greater than during exercise, with Sp_{O_2} falling an average of 12.9% during sleep compared with 4.5% during maximal treadmill exercise testing.[62] The presence of hypercapnia is a determinant of mortality.[63–65] Patients with COPD with chronic hypercapnia are more likely to be admitted to the hospital; once admitted, progressive clinical deterioration often follows.[66,67]

While alveolar hypoventilation likely accounts for most of the oxygen desaturations in COPD, changes in ventilation–perfusion matching and decreased end-expiratory lung volumes also have been described.[68,69] Ventilation–perfusion mismatching is suggested by discordance between a decreased Sp_{O_2} and a stable or slightly increased Pa_{CO_2}.[70] Changes in lung volumes, including a reduction in functional residual capacity, leading to closure of small airways have been suggested but studies are conflicting.[69] In addition, as patients with COPD typically have lower wakefulness Pa_{O_2} and lie closer to the steep portion of the oxyhemoglobin dissociation curve, they are more susceptible to significant nocturnal oxygen desaturation. This is particularly relevant in the presence of coexisting OSA, as discussed below.

Nocturnal oxygen desaturation in COPD has been associated with pulmonary hypertension, cardiac arrhythmias, and impaired sleep quality.[68,70] Poor sleep has been both subjectively reported and objectively demonstrated in patients with COPD with reduced sleep efficiency, delayed sleep onset, reduced total sleep time, sleep fragmentation, and a decrease in amounts of slow-wave and REM sleep.[71,72]

Long-term oxygen therapy (LTOT) used ≥15 h per day has been shown to improve mortality and quality of life in COPD patients with chronic resting hypoxemia.[73,74] However, correction of nocturnal hypoxemia in patients with COPD with only nocturnal oxygen desaturation has not been shown to consistently improve outcomes.[75–78]

For some time, there has been significant interest in the use of NIPPV in stable hypercapnic COPD. Patients with severe COPD with chronic hypercapnia are most likely to experience rehospitalization after a life-threatening episode of acute on chronic respiratory failure.[79,80] Correcting hypercapnia is an important intervention aiming at improving the prognosis of these patients; NIPPV is increasingly being used in this group.

McEvoy et al. randomized patients with severe COPD to NIPPV (average inspiratory pressure or IPAP of 13 cm H_2O and pressure support [PS] of 8 cm H_2O) plus LTOT or LTOT alone. There was only a marginal survival benefit in the NIPPV group[81] and no changes in Pa_{CO_2}.[81] The latter observation is likely explained by the low level of PS utilized, as PS is the driving force dictating tidal volume (Vt). Subsequent data have shown that nocturnal ventilatory strategies that aim to produce eucapnia or a sizable reduction in CO_2 utilizing high IPAP and PS, and that are able to provide a backup rate (i.e., high-intensity NIPPV), improve gas exchange and respiratory muscle function,[82–85] may provide a survival benefit,[86] and may reduce readmissions.[87] Murphy et al. in the HOT-HMV trial showed that NIPPV + LTOT in patients with persistent hypercarbia (Pa_{CO_2} >53 mm Hg) 2 to 4 weeks following a hospitalization for acute or chronic respiratory failure resulted in an increased time to readmission or death.[88]

NIPPV includes pressure-targeted and volume-target ventilatory modes. Current home ventilators are able to produce hybrid algorithmic combinations of these modes in which the ventilator continuously adapts its pressure delivery to achieve a preset target Vt or MV (volume assured pressure support or VAPS). This functionality to adapt to fluctuating respiratory mechanics during sleep and disease progression over time, in addition to automatically titrating end positive expiratory pressures (EPAP) to maintain upper airway patency (e.g., decreased effort and increased airway obstruction during REM sleep), results in steady ventilation. These adaptive pressure support modalities (e.g., iVAPS, Resmed; AVAPS, Philips) have been compared with bilevel PAP, either spontaneous (S) or spontaneous/timed (S/T). Six randomized controlled trials showed minimal reduction in Pa_{CO_2} (aggregated decline, 1.95 mm Hg; confidence interval [CI], 4.9 mm Hg lower to 0.40 mm Hg higher) with VAPS, but no difference in oxygenation.[89–95] Although physiologically attractive, auto-titrating modes are substantially more costly, and it is not clear if these devices can actually deliver steady ventilation in real-life conditions, as overestimation in exhaled Vt due to leak can result in algorithm-induced hypoventilation.[96] Until more evidence becomes available, it is not clear what mode or device is optimal, and selection of ventilatory support modality should be driven by cost, clinician level of understanding of newer modes, and patient comfort and support.

■ The Overlap Syndrome

The term *overlap syndrome* was coined by David Flenley in 1985 to describe the coexistence of COPD and OSA, although the original description alludes to a broader definition of coexisting hypoxemic lung disease and OSA.[68] It is of particular clinical relevance, given that greater sleep-related hypoventilation occurs than with either COPD or OSA alone.

The prevalence of the overlap syndrome is estimated at 1% of adults, but prevalence data vary with the definitions used for both COPD and OSA.[97] There is a lack of a standardized definition for the overlap syndrome.[98] Using an OSA definition of AHI ≥5 events/h and a Global Initiative for Chronic Obstructive Lung Disease (GOLD)-based definition of stage I COPD of FEV_1 >80%, a prevalence of 4% of males has been suggested, based on an OSA prevalence of 24% of males in the Wisconsin Sleep Apnea Study.[99] Evidence suggests that there is a similar prevalence of OSA in patients with COPD compared with the general population, with no increased association between at least mild COPD and OSA.[69,100,101]

Sanders et al. found no increased prevalence of SDB in patients with mild COPD; however, oxygen desaturation during sleep was more pronounced in patients with both conditions when compared with those with either disorder alone.[102] More recent studies report a relatively increased prevalence of OSA in patients with moderate to severe COPD,[103,104] as well as a higher rate of COPD and asthma in patients with OSA when compared with a matched control population, particularly among women.[105–107]

Patients with overlap syndrome have more significant nocturnal hypoventilation, with greater hypoxemia and hypercapnia than in COPD or OSA alone.[71,100,108,109] A decreased hypercapnic ventilatory response has been shown in these patients.[110] Pulmonary hypertension is more common and more severe than in either patients with COPD or OSA alone. In the latter, severe pulmonary hypertension is uncommon.[111]

The pattern of nocturnal desaturation in patients with overlap syndrome is characterized by intermittent desaturations and baseline hypoxemia, more so during REM sleep, commonly accompanied by reciprocal hypercarbia (Fig. 99-6). Consequently, the overlap syndrome should be considered in patients with either COPD or OSA with significant hypoxemia, hypercapnia, or pulmonary hypertension disproportionate to the severity of their disease. Patients with OSA/COPD overlap may have hypercapnia with a relatively preserved lung function compared to patients with COPD alone, in whom hypercarbia is usually associated with poor lung function.[113]

The diagnosis of overlap syndrome is important, given the increased morbidity and mortality compared with either COPD or OSA alone.[69] In an observational study, Marin et al.[114] compared 213 patients with untreated overlap syndrome with 210 patients with COPD alone and demonstrated increased mortality (relative risk, 1.79; 95% CI, 1.16–2.77) in the overlap group over a median follow-up of 9.4 years. COPD has been shown to result in increased mortality in OSA in several studies.[115] Data from the 2005–2008 National Health and Nutrition Examination Survey (NHANES), which included 10,388 subjects, revealed that although having OSA/COPD overlap syndrome was associated with higher likelihood of death than COPD alone (HR, 1.5), the difference was not statistically significant.[116]

Some specific clinical features (phenotypes) in patients with COPD may help predict the likelihood of overlap syndrome. The emphysema-predominant phenotype (low BMI, hyperinflation, altered gas exchange) is less likely to have OSA, as hyperinflation

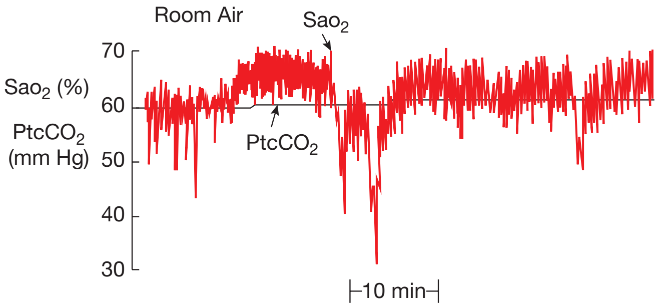

Figure 99-6 Oxyhemoglobin and transcutaneous CO_2 ($PtcCO_2$) tracing in OSA COPD overlap: note hypoxemia at baseline, cyclic desaturation due to intermittent airway obstructions, and reciprocal $PtcCO_2$ elevation. *(Adapted with permission from McNicholas WT. Chronic obstructive pulmonary disease and obstructive sleep apnoea—the overlap syndrome. J Thorac Dis. 2016;8(2):236–242.)*

reduces the critical closing pressure of the upper airway during sleep by means of mechanical tracheal traction.[117] On the other hand, the chronic bronchitis phenotype (higher BMI, altered gas exchange, cor pulmonale) has a lower respiratory drive that often leads to hypercarbia, in addition to rostral fluid shifting resulting in airway narrowing and increased prevalence of OSA.[118] The reality is that the vast majority of patients share both phenotypes, and these mechanisms often imbricate, leading to a rather broad spectrum of clinical overlap.

There are also data examining the potential overlap of systemic inflammation, oxidative stress, and leukocyte dysfunction implicated in both COPD and OSA and the resultant impact on cardiovascular disease.[98] OSA promotes lower airway inflammation in patients with COPD,[119] and chronic intermittent hypoxia contributes to inflammation and oxidative stress.[120]

Given the clinical implications of the overlap syndrome, symptoms and signs suggestive of OSA should be included in the evaluation of all patients with COPD. If there is any clinical suspicion, a full in-laboratory sleep study should be performed in eucarbic COPD. Unattended portable sleep studies have not yet been validated in the COPD population.[121] Similarly, nocturnal oximetry alone cannot reliably discriminate nocturnal oxygen desaturation secondary to COPD alone, OSA, or a combination of the two, and given differences in treatment based on the underlying pathophysiology, it is not recommended for assessment.

Treatment of the overlap syndrome is directed at the underlying disorders. Recent studies have suggested a survival benefit in patients with overlap syndrome with CPAP,[114,122] but these studies were not randomized. Nevertheless, CPAP is currently the accepted standard for the treatment of overlap syndrome. It has been suggested that CPAP, in addition to relieving upper airway obstruction, off-loads the respiratory muscles, thereby reducing hypoventilation, oxygen consumption, and CO_2 production by respiratory muscles; additionally, it may also offset intrinsic PEEP in patients with severe COPD. CPAP alone may not fully correct hypoxemia, requiring addition of supplemental oxygen; however, oxygen alone is not recommended for the overlap syndrome[123] because it can potentially worsen hypercapnia (hyperoxic hypercarbia) by relieving hypoxic vasoconstriction and shifting the pulmonary circulation to poorly ventilated lung segments, resulting in increased dead space ventilation.[124]

SLEEP-RELATED HYPOVENTILATION IN NEUROMUSCULAR DISORDERS

Sleep-related hypoventilation is common in neuromuscular disorders[125] including, but not limited to, amyotrophic lateral sclerosis (ALS), spinal muscle atrophies (SMA), post-polio syndrome, muscular dystrophies, congenital muscular dystrophy, myotonic dystrophy, metabolic myopathies, Guillain-Barré syndrome, and myasthenia gravis. The effects of neuromuscular disorders on ventilation are covered in Chapter 84. Sleep-related breathing disorders generally precede daytime ventilatory failure, and the full spectrum from obstructive and central respiratory apneas to hypoventilation is found.

The mechanisms for sleep-related hypoventilation in neuromuscular disorders are multifactorial. Respiratory muscle weakness plays a central role. The type and severity of sleep-related breathing disorders usually parallel the extent and distribution of respiratory muscle weakness. Sleep hypoventilation often develops when the supine vital capacity is $<60\%$ of the predicted value or the maximal inspiratory pressure is <34 cm H_2O.[126] Patients with diaphragmatic weakness depend on recruitment of accessory inspiratory muscles and expiratory abdominal muscles and are particularly susceptible to significant hypoventilation during REM sleep in which there is relative atonia of these skeletal muscles.

Weakness of the upper airway musculature can cause obstructive events, further exacerbated by an imbalance between the inspiratory force generated by the inspiratory muscles and activity of the muscles responsible for stabilizing the upper airway.[127] With progressive respiratory muscle weakness the number of respiratory events and the AHI may decline in ALS.[128] This may reflect an inability of the inspiratory respiratory muscles to generate pressures above the closing pressure of the upper airway, resulting in fewer obstructive events. Bulbar muscle dysfunction and aspiration risk have not been shown to be significantly associated with severity or type of sleep-related breathing disorders in ALS.[127,129,130]

Abnormalities of ventilatory control have been also described in certain neuromuscular disorders, including myotonic dystrophy and congenital myopathy.[127] The hypercapnia and bicarbonate retention caused by nocturnal hypoventilation can further depress the respiratory drive, exacerbating sleep-related hypoventilation. Sleep fragmentation with shorter total sleep time, frequent arousals, and a reduction in or complete suppression of REM sleep have been described in neuromuscular disorders.[131] This sleep fragmentation and sleep loss may further suppress the arousal response and worsen hypoventilation.

Given the pervasiveness of sleep-related hypoventilation in neuromuscular disorders, a detailed sleep history is an essential component of any clinical evaluation. Early in-laboratory polysomnography with continuous CO_2 monitoring is indicated in this patient population, as sleep-related hypoventilation may precede diurnal hypoventilation and hypercarbia. NIPPV has been shown to improve sleep quality, quality of life, and mortality in various neuromuscular disorders, and management of neuromuscular respiratory muscle dysfunction is covered in Chapter 84.[131–134] However, the optimal criteria for initiation of NIPPV for sleep-related hypoventilation in neuromuscular disorders remain uncertain. The advent of sophisticated home ventilators and improved interfaces (masks) allows providing both nocturnal and diurnal noninvasive ventilation safely to these patients. These ventilators allow transition from different modes of ventilation using one device. The use of ventilatory algorithms, such as VAPS (see above), have also improved how ventilatory support is delivered as it automatically adapts the level of support as the disease progresses. The ability to remotely monitor physiologic ventilatory outcomes through almost real-time cloud-based data generated by these ventilators allows clinicians to change parameters and predict complications (e.g., abrupt changes in Vt or RR may suggest airway obstruction or infection). $PtcCO_2$ can also be measured in the home setting in lieu of in-lab titrations.

SLEEP-RELATED HYPOVENTILATION IN RESTRICTIVE CHEST WALL DISORDERS

Chest wall deformities, in particular scoliosis, often accompany neuromuscular disorders and can contribute to sleep-related hypoventilation. Nonmuscular diseases of the chest wall are reviewed in Chapter 83.

Patients with scoliosis, a rotational deformity of the spine, have reduced chest wall and lung compliance, increased work of breathing, respiratory muscle weakness, ventilation–perfusion mismatching, and reduced respiratory drive.[135] The degree of respiratory impairment is associated with severity of spinal deformity. Respiratory failure is, therefore, uncommon if the Cobb angle (a radiographic measure of spinal curvature in the coronal plane, calculated from two lines drawn perpendicular to lines drawn through the middle of the two vertebrae at the top and bottom of the curved segment) is less than 100 degrees.[136] Sleep is a vulnerable period in patients with scoliosis, and as with neuromuscular disorders, gas exchange is worst during REM sleep.[137–140] While central hypoventilation is more common, airway obstruction also can occur. Patients with scoliosis breathe at low lung volumes, and lower airway caliber is proportional to lung volumes. In addition, secondary cervical curvature can displace the intrathoracic trachea to cause significant upper airway obstruction during sleep. Therefore, clinical evaluation for sleep-related hypoventilation is necessary in this population, followed by polysomnography when a sleep-related breathing disorder is suspected. NIPPV has been shown in small studies to improve gas exchange in restrictive chest wall disorders; however, results on changes in sleep architecture and sleep quality have been mixed.[137,138,140–142]

CONCLUSION

An understanding of normal sleep-associated changes in ventilation is essential in identifying sleep-related hypoventilation syndromes and appreciating the potential vulnerability of the sleep period for patients with underlying cardiopulmonary disorders, morbid obesity, neuromuscular disease, and restrictive chest wall disorders. Consequently, a comprehensive sleep evaluation should be incorporated in the clinical evaluation of each of these high-risk patient populations. This is particularly relevant given the recent advances in NIPPV treatment.

CHAPTER 100

Changes in the Cardiorespiratory System During Sleep

Indira Gurubhagavatula
Susheel P. Patil

As outlined in Chapter 12, sleep occurs in distinct states classified broadly as non–rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. These states occur in a temporally organized fashion across the sleep period, with NREM dominating during the initial hours of sleep and REM during the later hours of sleep. REM sleep cycles occur in 90- to 120-min cycles, with a typical healthy adult experiencing 3 to 5 cycles during the major sleep bout. Specific alterations in autonomic regulation occur during REM sleep, which may at least partly explain the higher frequency of occurrence of myocardial infarction and ischemic stroke during early morning hours,[1–3] when REM sleep predominates. This chapter presents additional information on alterations in cardiopulmonary function during sleep.

CHANGES IN CARDIOVASCULAR CONTROL DURING SLEEP

During NREM sleep, heart rate normally slows by 5% to 10%,[4] and blood pressure drops by about 10%.[4] These changes are most prominent in the deepest stage of NREM sleep,[4] known as slow wave sleep (stage N3).[5] The mechanism for this decline was elucidated by the seminal study of Somers et al.[4] using microneurography to record sympathetic bursts in the peroneal nerve in healthy humans during wake and in the different stages of sleep (Fig. 100-1). These studies confirmed a fall in sympathetic activity during NREM sleep, which is responsible for the drop in blood pressure, cardiac output, and systemic vascular resistance.[4] The fall in sympathetic activity is accompanied by an increase in parasympathetic (vagal nerve) activity that is believed to be responsible for the bradycardia of NREM sleep.[6] Fundamental to NREM sleep is that the balance of parasympathetic/sympathetic activity is altered, with parasympathetic tone being dominant, thereby affecting heart rate variability during sleep. The high-frequency component of heart rate variability is said to reflect parasympathetic activity, while the low-frequency component is related to sympathetic activity.[4] Thus, during NREM sleep compared with wakefulness and REM sleep, there is an increase in the high-frequency component and a marked reduction in the low-frequency component of heart rate variability.[4]

Changes in cardiovascular variables in REM sleep differ from NREM sleep. During REM sleep, there are surges of sympathetic activity such that heart rate and blood pressure return to, or may sometimes even exceed, wakefulness levels.[4] This phenomenon has been shown by direct recordings of sympathetic nerve activity (SNA) in humans (Figs. 100-1 and 100-2).[4] Thus, during REM sleep the high- and low-frequency components of heart rate variability are similar to those found during wakefulness.[4]

During REM sleep there is also activity that occurs in phasic bursts associated with rapid eye movements (REMs), hence the name for the state. Phasic bursts of activity (phasic REM) can lead to brief, sudden increases in heart rate and blood pressure that are mediated by surges in sympathetic activity,[4,6–8] which are similar to or can exceed waking levels.[4] In addition to changes in SNA, denervation experiments in cats demonstrate that neural reflexes may also be at play, resulting in sudden, baroreflex-mediated periods of decrease in heart rate.[6] These changes have pathophysiologic consequences. During surges of heart rate, there are also increases in coronary blood flow.[7,8] However, increases in coronary blood flow may be insufficient to meet the additional myocardial demands that occur with the increase in heart rate, thereby compromising the myocardium. Moreover, in animal models of severe coronary stenosis, phasic decreases in coronary arterial blood flow are found when heart rate increases in REM sleep.[7] Such changes may play a role in the known diurnal rhythm of timing of reported acute cardiac events in humans.[1–3]

Episodes of abrupt heart rate decelerations can also occur during REM sleep. In addition to baroreceptor-mediated decelerations, sudden slowing of the heart rate may be a result of reduction in central autonomic input to the heart, an increase in vagal tone, or both.[9] At the extreme, brief episodes of asystole in phasic REM sleep have been described in otherwise healthy adults.[10]

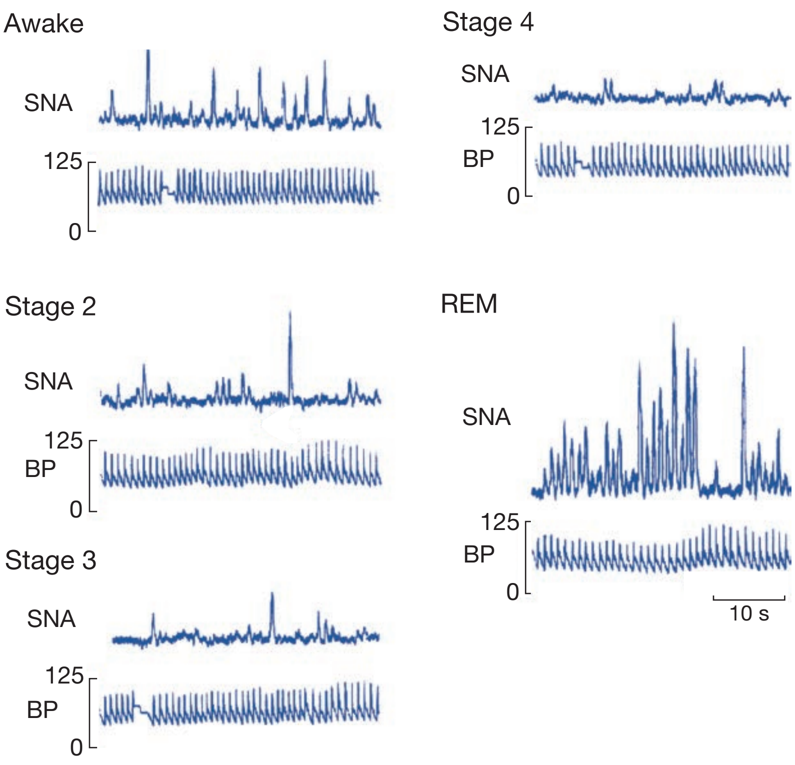

Figure 100-1 Alterations in recorded bursts of sympathetic nerve activity (SNA) and blood pressure (BP) in wakefulness, different stages of non–rapid eye movement sleep (NREM) (stages 2–4), and rapid eye movement (REM). With deepening of NREM sleep, there is progressive loss of sympathetic activity, which is virtually absent in slow-wave sleep (stage 4). Sympathetic activity returns in REM but is highly variable. *(Reproduced with permission from Somers VK, Dyken ME, Mark AL, et al. Sympathetic-nerve activity during sleep in normal subjects. N Engl J Med. 1993;328(5):303–307.)*

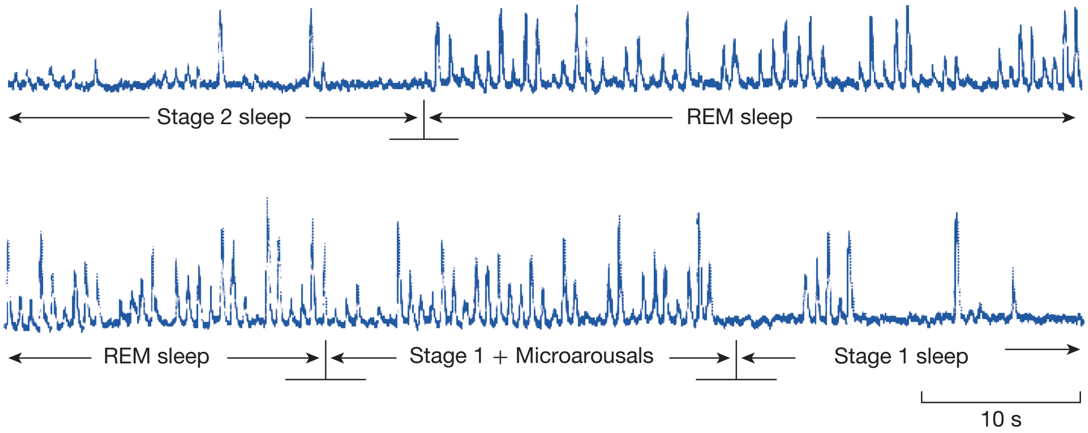

Figure 100-2 Changes in recorded sympathetic nerve bursts in a healthy human during transitions between different sleep stages. There are more bursts—that is, more sympathetic activity—in REM sleep compared with stage 2 NREM sleep (top panel) and more activity in stage 2 sleep when it is transitional with many microarousals than when fully established (bottom panel). *(Reproduced with permission from Somers VK, Dyken ME, Mark AL, et al. Sympathetic-nerve activity during sleep in normal subjects. N Engl J Med. 1993;328(5):303–307.)*

CHANGES IN VENTILATION AND ITS CONTROL WITH SLEEP

As with the cardiovascular system, there are important changes in ventilation during sleep, which differ between NREM and REM sleep.[11,12] During NREM sleep, ventilation declines. The various studies in this area have been summarized by Krieger et al.[13] All studies have reported decreased ventilation, although the magnitude of change varies from study to study (see summary in Fig. 100-3). In general, there is a decline in tidal volume while the change in respiratory rate is more variable (see Table 1 in Krieger et al., 1990).[13]

Ventilation in REM sleep is also consistently less than in wakefulness; some studies report a small increase in ventilation in REM compared with NREM sleep (0.9%–7.1%), whereas other studies report a further decrease (−1.1% to −10.8%).[13] The variability between studies is likely related to the variability of ventilation in REM sleep itself. As in the cardiovascular system, there are changes in ventilation in association with the phasic events of REM sleep.[14] Both acceleration and decelerations of respiratory rate are observed as are declines in ventilation. These effects vary between subjects (Fig. 100-4),[14] with some subjects showing large reductions in inspiratory flow and increased respiratory frequency during REMs and others showing only minor changes.[14]

The changes in NREM sleep in normal humans are largely the result of increases in upper airway resistance.[15] This resistance progressively increases from stage N1 to stage N3 NREM sleep (Fig. 100-5). This increase in resistance is associated with a decrease in upper airway muscle activity in muscles such as the genioglossus[16–20] and tensor palatini[15] in the soft palate. During REM sleep, pharyngeal muscle activity is attenuated via sleep-specific motor inhibition,[18] predisposing individuals to obstructive sleep apnea.

The neural control of upper airway motor neurons is complex and involves inputs from many premotor neurons originating in the forebrain, midbrain, pons, and medulla,[21] which communicate with upper airway motor neurons via a diverse group of neurotransmitters. Identification of the neurochemical changes that are responsible for reduced upper airway motor tone can elucidate promising pharmacologic targets for obstructive sleep apnea. Research has demonstrated that the neurochemical drive to upper airway motor neurons varies with behavioral state and in fact is quite distinct in NREM relative to REM sleep. In NREM sleep, reduced noradrenergic input from the pons[16,19,20] contributes to reduced upper airway tone. Noradrenaline as a neuromodulator may play this role by potentiating glutamatergic excitation,[16] rather than via direct excitation, as measured by masseter muscle activity. Muscarinic inhibition of the hypoglossal motor pool prevents the inhibition of genioglossus activity throughout REM sleep.[18] During REM sleep, muscarinic receptors for acetylcholine linked to G protein–coupled inwardly rectifying potassium (GIRK) channels have been shown to be important.[18] Thus, preventing apneas in both NREM and REM sleep will likely require modulation of both noradrenergic and cholinergic neurotransmitters as well as potentially specific GIRK channels.

Individuals with and without upper airway obstruction during sleep demonstrate increased Pa_{CO_2} in sleep. These findings support the concept that central ventilatory drive is altered by sleep state. Although an increase

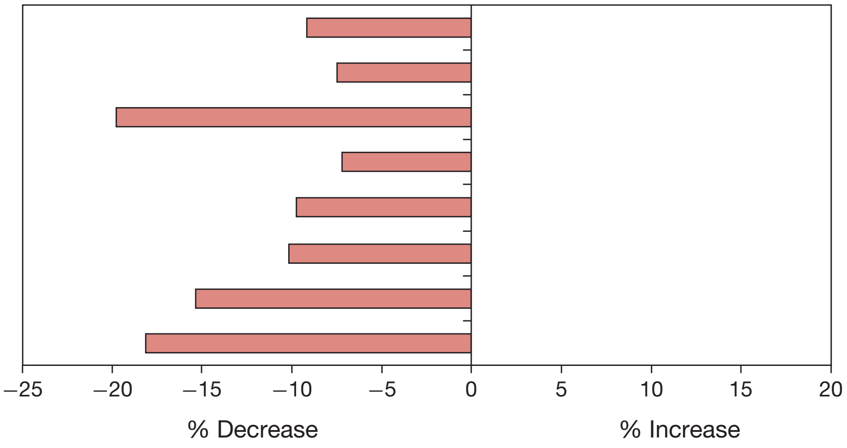

Figure 100-3 Percentage change in minute ventilation from wakefulness to NREM sleep in several different studies. There is some variation among studies in the magnitude of the drop in ventilation in NREM sleep, but all studies show a decline. *(Data from Krieger J, Maglasiu N, Sforza E, et al: Breathing during sleep in normal middle-aged subjects. Sleep. 1990;13(2):143–154.)*

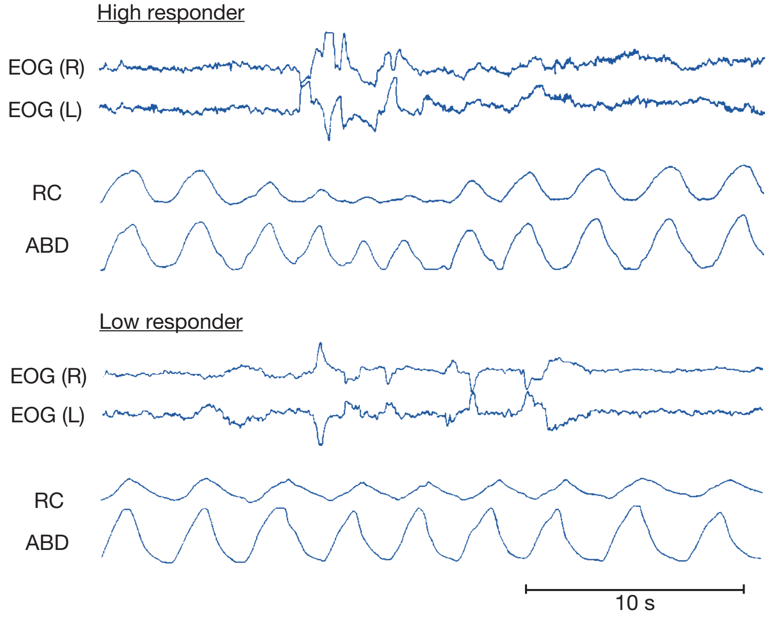

Figure 100-4 Changes in respiration during REM sleep. The data shown are for two normal healthy adults. The top traces are right and left electrooculogram [EOG (R) and EOG (L)] that show phasic eye movements during REM sleep. The bottom traces are ribcage (RC) and abdominal (ABD) motion. The subject in the top panel *(High Responder)* has a marked fall in ribcage and to a lesser extent abdominal motion in association with the eye movements. The subject in the bottom panel *(Low Responder)* has little alteration in ventilatory movements during these phasic eye movements. *(Reproduced with permission from Neilly JB, Gaipa EA, Maislin G, et al. Ventilation during early and late rapid-eye-movement sleep in normal humans. J Appl Physiol. 1991;71(4):1201–1215.)*

in upper airway resistance is the major mechanism, it is not the only mechanism, since even in laryngotomized subjects with tracheostomies, which bypass the upper airway, P_{CO_2} increases in NREM sleep compared to wakefulness.[22] During sleep, the relative importance of the increase in upper airway resistance reflects differential neural control of upper airway muscles[18–20,23,24] and respiratory pump muscles such as the diaphragm. The former is much more coupled to changes in the sleep–wake state, while the latter is more affected by chemical control rather than variations in state (Fig. 100-6). The relative balance of drive to the upper airway muscles relative to the respiratory pump muscles is partly why obstructive sleep apnea is more common than central sleep apnea.

Sleep also alters the ventilatory response to hypoxia and hypercapnia. These effects on ventilatory drive are in part sex-specific. The ventilatory response to hypoxia declines in NREM sleep compared to wakefulness in men,[25,26] but it appears to remain the same in wakefulness and NREM sleep in women.[27] This difference in ventilatory response was attributed to a higher level of ventilation during wakefulness in men than women, with comparable levels in NREM sleep.[27] The ventilatory response to hypoxia is lower in REM sleep than in NREM, in both men and women.[25–27] Likewise, the slope of the ventilatory response to carbon dioxide is reduced in NREM sleep by as much as 50%[28] compared to wakefulness and further reduced in REM sleep. However, there is no compelling evidence that there is an alteration in central neural response to chemical stimuli, as changes in upper airway resistance offset the increases in ventilation produced by increased diaphragmatic neural output.

As a consequence of the changes in ventilation with sleep onset, Pa_{CO_2} rises typically from a normal value of 40 mm Hg by a few mm Hg in NREM sleep.[29] The magnitude of increase in Pa_{CO_2} is a function of the responsiveness of the system to CO_2 during wakefulness; subjects with low ventilatory responses to CO_2 have larger increases in Pa_{CO_2} during NREM sleep than do subjects with high responsivity (Fig. 100-7).[29]

Parallel to the increase in Pa_{CO_2}, the Pa_{O_2} can fall during sleep. In healthy individuals living at sea level, the Pa_{O_2} falls by a few mm Hg but does not fall to a level where significant desaturations occur. However, in persons with low Pa_{O_2} during wakefulness who operate closer to the "knee," or inflection point of the oxygen saturation curve, the fall in Pa_{O_2} with sleep onset may lead to a significant hypoxemia. For example, patients with chronic obstructive pulmonary disease may require supplemental oxygen during sleep but not during wakefulness. The severity of sleep-related hypoxemia will also vary with sleep state–dependent changes in functional residual capacity

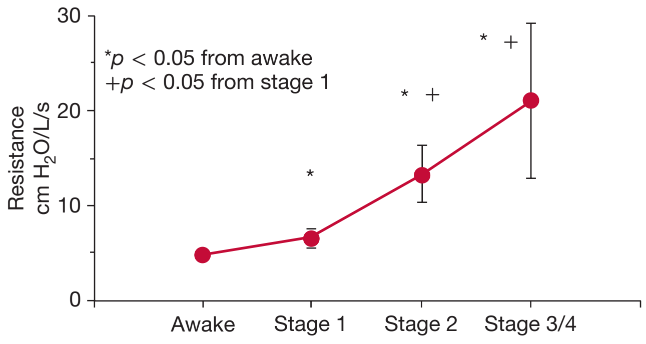

Figure 100-5 Upper airway resistance increases progressively on going from wakefulness to the deeper stages of NREM sleep. *(Data from Tangel DJ, Mezzanotte WS, White DP. Influence of sleep on tensor palatini EMG and upper airway resistance in normal men. J Appl Physiol 1991;70(6):2574–2581.)*

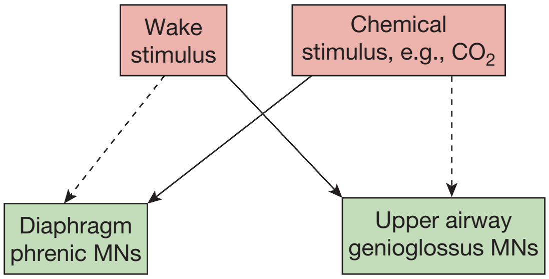

Figure 100-6 Schematic diagram illustrating the relative role of the "wakefulness drive" to breathe and that related to the chemical control system determined by Pa_{CO_2} and Pa_{O_2}. The diaphragm is only little affected by the wakefulness drive *(dashed line)* and is predominantly responding to chemical stimuli *(thick line)*. In contrast, upper airway motor neurons, such as genioglossus, are more affected by the "wakefulness stimulus" coupled to sleep state. MN, motor neurons.

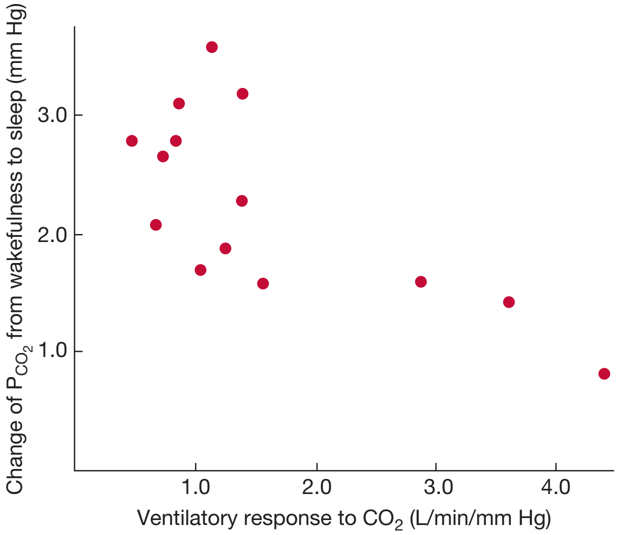

Figure 100-7 Relationship between the increase in Pa_{CO_2} that occurs in normal subjects in going from wakefulness to stages 1 and 2 NREM sleep and the CO_2 ventilatory response in wakefulness. Persons with the lowest ventilatory responses show the largest change in Pa_{CO_2} in going to sleep. *(Adapted with permission from Gothe B, Altose MD, Goldman MD, et al. Effect of quiet sleep on resting and CO_2-stimulated breathing in humans. J Appl Physiol Respir Environ Exerc Physiol. 1981;50(4):724–730.)*

(FRC). When FRC is low as a consequence of obesity or intrinsic lung disease, the fall in Pa_{O_2} will be greater than expected for the increase in Pa_{CO_2}, given the reduced reserve of oxygen in the lung.

Another major change that occurs during NREM sleep is an increase in the CO_2 apnea threshold. The apnea threshold is the Pa_{CO_2} at which there is insufficient chemical drive and ventilation ceases. During the awake state, there is a wakefulness drive to ventilation. This drive is lost during sleep, and instead, the ventilatory drive is primarily coupled to the chemical stimuli for respiration that is, increased Pa_{CO_2} and reduced Pa_{O_2}. During wakefulness, Pa_{CO_2} can be reduced by assisted ventilation to values as low as 20 mm Hg and rhythmic ventilation will be maintained;[12] thus, the CO_2 apnea threshold during wakefulness is extremely low. In contrast, during NREM sleep, the Pa_{CO_2} only needs to be reduced to values close to the normal awake Pa_{CO_2} (from 42–45 to 38–40 mm Hg) and ventilation will cease.[12] Indeed, the normal increase in Pa_{CO_2} that occurs during NREM sleep is often necessary to maintain rhythmic ventilation.

This NREM sleep–related increase in the apnea threshold has profound implications. In situations in which ventilation is stimulated—for example, by hypoxia—Pa_{CO_2} may be reduced below the apnea threshold typical for normoxic conditions, creating a state of increased vulnerability to central apneas.[12,30] It is likely that idiopathic central apnea during sleep occurs in association with hypocapnia.[30,31] This hypocapnia may be the result of chronic hyperventilation, which is probably related to augmented central and peripheral respiratory drive, which predisposes to respiratory control system instability.[30] If this is the mechanism for these apneas, increase in the Pa_{CO_2} should abolish them. This has been demonstrated by addition of small amounts of CO_2 to the inspired gas in subjects with idiopathic central apnea.[12] Relative hypocapnia is also a risk factor for the development of Cheyne–Stokes respiration in patients with congestive heart failure.[30,31] The "CO_2 reserve," which is defined as the difference between eupneic Pa_{CO_2} and the Pa_{CO_2} at the apneic threshold, has been shown to be a determinant of breathing stability during sleep. Larger reserves result in more stable ventilation, and lower reserves result in less stable ventilation.[32]

The specific cellular and neurochemical mechanisms for this NREM sleep–related change in the apnea threshold are currently unknown. Conceptually, however, it may be considered within the same category as the so-called wakefulness stimulus for breathing. Brain stem neuronal groups, such as the locus coeruleus and raphe nuclei in which the major transmitters are norepinephrine and serotonin, respectively, exhibit decreased activity with sleep.[33] Since both neurotransmitters have important excitatory effects at various levels of the central respiratory control system, these neuronal groups likely represent major components of the wakefulness stimulus and may play a role in establishing the apnea threshold.

AROUSAL DURING SLEEP

During sleep various sensory stimuli, including auditory and tactile,[34] can lead to a sudden change in sleep state to a lighter stage of sleep or complete wakefulness. Arousal can be detected with abrupt changes in the electroencephalogram.[35] Arousal also results in an increase in heart rate and blood pressure as well as an increase in ventilation,[36] a response that is independent of CO_2[37] and that decreases with age.[38] So-called subcortical or brain stem arousals—arousals with abrupt changes in cardiopulmonary variables but no change in the electroencephalogram—also can arise, sometimes observed following disordered breathing events.[39] Arousals can produce marked increases in activity of the upper airway muscles than in the diaphragm,[40] producing a ventilatory overshoot that is transiently higher than during stable wakefulness.

Respiratory stimuli, such as airway occlusion, increased upper airway resistance, hypoxia, and hypercapnia, also can lead to arousal during sleep.[34,39] Perhaps unintuitively, isocapnic hypoxia is a poor stimulus to arousal. Individuals can remain asleep without interruption even when Sa_{O_2} values fall as low as 70%.[39] The degree of respiratory effort, however, appears to be the major stimulus to arousal.[39] Increases in respiratory neural output above a threshold are closely correlated with arousal threshold for a given individual, with respiratory effort that is independent of the causes of this increased effort, whether stimulated by added inspiratory resistive load, hypoxia, or hypercapnia.[33,38] Not all arousals are identical. Azarbarzin et al. have developed a scoring approach that allows the magnitude of arousal to be quantified on a scale of 1 to 9.[41] A score of 1 indicates a "weak" arousal, while 9 is a major arousal with marked increases in muscle tone (Fig. 100-8). The heart rate response to arousal is greater with more severe arousals compared with less severe arousals.[41] The magnitude of the heart rate response to arousal is a subject-specific trait,[42] that is, the magnitude of response is stable within a subject from night to night at a fixed arousal intensity, but it varies between subjects (Fig. 100-9). Studies in twins show that this is also a heritable trait,[43] but the relevant genes have not yet been identified. This difference in response likely reflects the sympathetic response to arousals. Heart rate response to arousal has been shown to be predictive of who with obstructive sleep apnea (OSA) gets future cardiovascular events.[44] Individuals with higher heart rate response to arousals have increased cardiovascular mortality.[44]

PERIODICITIES OF VENTILATION IN LIGHT NREM SLEEP

Periodic (oscillatory) ventilation is more likely to occur during light NREM sleep (stages N1 and N2) than in slow-wave sleep (stage N3).[45–47] (Previously NREM was divided into four stages. Scoring criteria have changed such that NREM is now divided into three stages—N1, N2, and N3.) This is highly relevant to the problem of obstructive sleep apnea[47] (Chapter 98); most apneas occur in stages N1 and N2 sleep.[47] If an individual with sleep apnea is able to enter stage N3 sleep, regular ventilation resumes and apneas are less likely to occur.[47] Oscillatory ventilation is also typically observed during hypoxia, as in lung disease or at high altitude, and in certain cardiovascular diseases.[48]

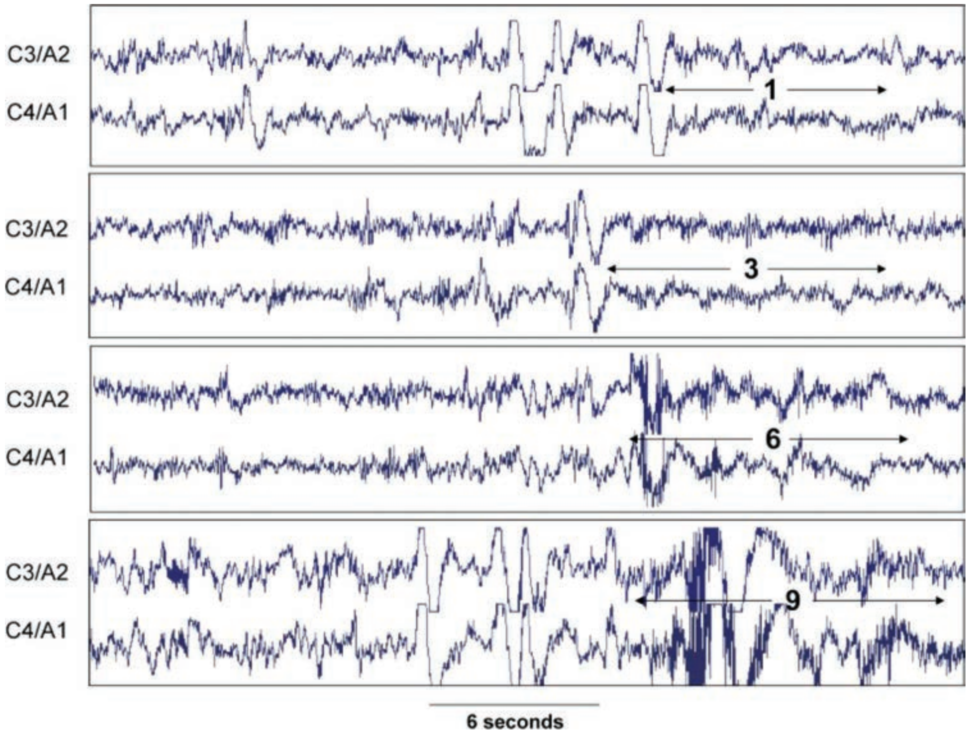

Figure 100-8 Examples of changes in EEG with arousals of different intensities. The examples shown are from the same subject and show arousals with intensity one (top panel), 3, 6, 9 (bottom panel). C31A2 and C41A1 are for control recordings of the electroencephalogram. *(Reproduced with permission from Azarbarzin A, Ostrowski M, Hanly P, et al. Relationship between arousal intensity and heart rate response to arousal. Sleep. 2014;37(4):645–653.)*

Ventilation may become periodic because of dynamic properties of the chemical feedback system that controls respiration.[46,49,50] As in any feedback system, the critical determinants of this unstable (oscillatory) behavior are the overall response (gain) of the control system and the time delay (phase lag) between the plant and the controller. For the respiratory system, the plant is the gas exchange apparatus in the lung; the controllers are the peripheral and central chemoreceptors; and the controlled variables are the arterial blood–gas tensions, Pa_{CO_2} and Pa_{O_2}. Thus, in the case of the respiratory control system, time delay is the blood circulation time between the lung and the peripheral/central chemoreceptors.[49]

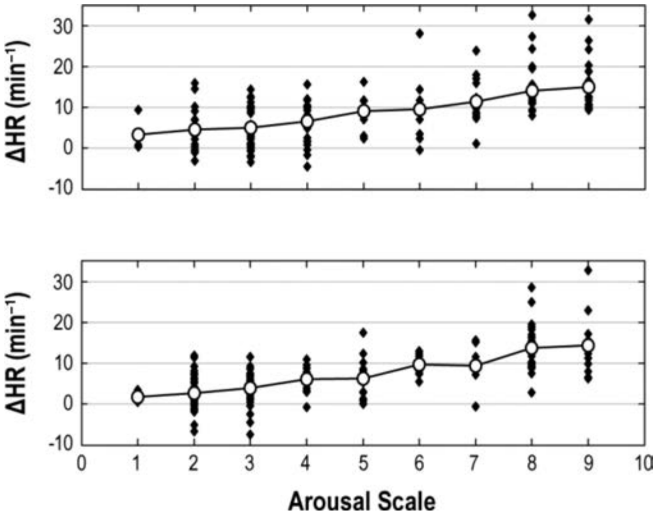

Figure 100-9 Changes in heart rate (ΔHR) with arousals of different intensities (1 to 9) in a sample subject. Data were obtained in the same subject on two separate nights of recording (top and bottom panels). Each solid dot is one or more arousal at a given intensity. The line shows the average heart rate response at arousals of different intensity. Within a subject the heart rate response to arousal is reproducible from night to night. *(Reproduced with permission from Azarbarzin A, Ostrowski M, Younes M, et al. Arousal Responses during Overnight Polysomnography and their Reproducibility in Healthy Young Adults. Sleep. 2015;38(8):1313–1321.)*

The importance of this delay is illustrated in Fig. 100-10 for a situation in which a disturbance to the ventilatory control system leads to a change in Pa_{CO_2}. In the absence of a circulatory delay, the control system responds immediately to the perturbation by adjusting ventilation to correct the change in Pa_{CO_2} (Fig. 100-10A). In contrast, with circulatory delays, the controller may act to inadvertently promote a cyclical disturbance (Fig. 100-10B) through inappropriate corrections, due to the delay in the altered Pa_{CO_2} level reaching the chemoreceptors. For example, when the Pa_{CO_2} level in the blood leaving the lung is low, the controller should respond by reducing ventilation, returning the Pa_{CO_2} to the eupneic level. If, however, the circulatory delay is significant such that the low Pa_{CO_2} signal reaches the sensor when the Pa_{CO_2} of the blood leaving the lung is already higher (e.g., due to the presence of an external perturbation or already existing oscillations, as in Fig. 100-10), the controller will act incorrectly to reduce ventilation and further increase the Pa_{CO_2}. Such a situation potentially promotes self-sustaining periodic ventilation. Thus, the circulatory time delay determines not only whether periodic ventilation will or will not occur, but also the period, that is, duration, of the oscillation.

Periodic ventilation would not occur if the control system failed to respond, or responded weakly, to breathing perturbations. Thus, the magnitude of the gain in responding to alterations in Pa_{CO_2} is also critical in determining whether ventilatory instability will occur. The key variable is overall loop gain. This is defined as the product of the controller response (the change in ventilation per unit change in Pa_{CO_2}, i.e., CO_2 sensitivity) and the plant gain (the change in Pa_{CO_2} per unit change in ventilation).[49] High overall loop gain is also one of the physiologic risk factors for obstructive sleep apnea.[51] It has been suggested that overall loop gain can be assessed from analysis of data obtained from routine sleep studies, based on a simple model of ventilatory control.[52,53] But this model has been criticized since the assumptions underlying this simple model are considered "untenable."[54] There are currently no data as to the reliability of this measure, that is, will the same result be obtained in

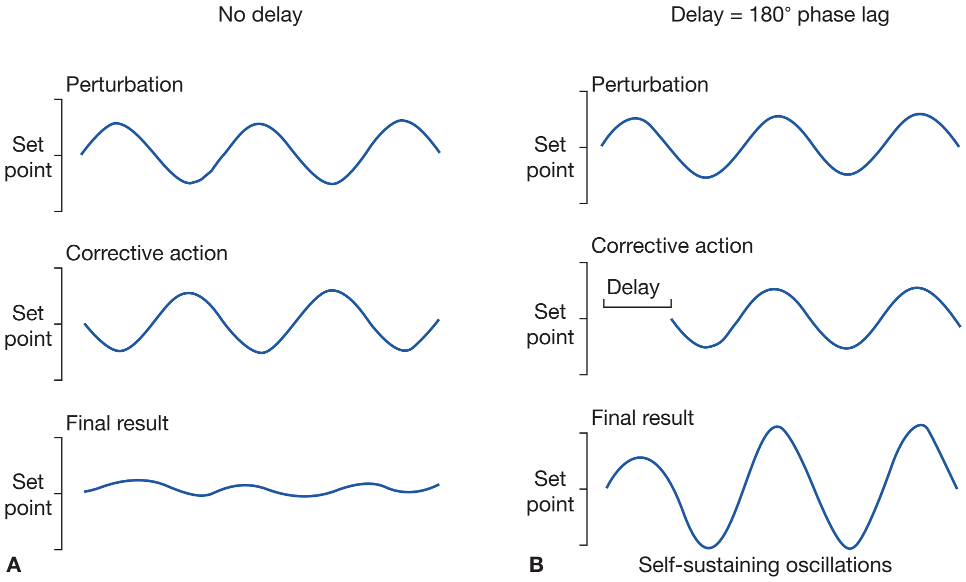

Figure 100-10 Implications for a control system with a delay between the plant and the control system. The left panel (**A**) shows how a control system will respond to a sinusoidal perturbation when there is no delay. The perturbation is essentially neutralized. The right panel (**B**) shows how a control system acts if it has a delay that results in the corrective action being 180 degrees out of phase with the perturbation. In this case, the controller's action acts to sustain, and not to neutralize, the original sinusoidal perturbation.

repeat testing of the same individual? Moreover, there are limited data validating this measure by comparison to "gold standard" measures. It has been argued that for individuals with OSA with high loop gain, use of intraoral devices for treatment is ineffective.[55,56]

Periodic breathing occurs in clinical situations, particularly in hypoxic subjects (e.g., patients with lung disease) and normal sojourners at high altitude.[57] Hypoxia increases the controller gain, increasing ventilatory instability. The period of the oscillations in ventilation induced by hypoxia is on the order of 20 s, much shorter than those typically seen in patients with obstructive sleep apnea or in Cheyne–Stokes respiration (typically 60 to 90 s). As noted earlier, abnormally prolonged circulatory time is one of several mechanisms that contribute to ventilatory oscillations that occur during sleep in patients with severe congestive heart failure (e.g., Cheyne–Stokes respiration).[58,59]

In addition to mechanisms that are related to instability of the chemical control system for ventilation, sleep–wake state instability (i.e., frequent transitions between the wake and sleep state) can produce oscillations in ventilation.[12,14,25–28,49] As discussed in the preceding section, at the onset of sleep, ventilation decreases[11,13,29] as upper airway resistance increases[15] with concomitant increases in Pa_{CO_2}; the increase in Pa_{CO_2} may, in turn, directly or indirectly interfere with the normal progression towards stable sleep. For example, an abrupt change in sleep state may occur as a result of partial airflow obstruction and increased respiratory effort, leading to a transition to a lighter stage of sleep, that is, an arousal. Upon arousal, ventilation increases, upper airway resistance decreases, and Pa_{CO_2} drops. On returning to sleep the whole cycle may repeat itself. Sleep-wake instability is more likely to arise if the ventilatory response to CO_2 is low, since the Pa_{CO_2} increases more at sleep onset and is more apt to drive the level of respiratory effort to a point at which an arousal from sleep occurs. The period of ventilatory oscillation caused by this mechanism is longer than that seen with chemical instability, at about 60 to 90 s. This mechanism likely contributes to recurrent upper airway obstruction and periodic breathing in patients with low ventilatory responses to CO_2 (e.g., patients with hypothyroidism, in whom central and obstructive apneas are common).[45,49]

CIRCADIAN CLOCKS IN THE CARDIOVASCULAR SYSTEM AND LUNG

While much is known about the physiology of cardiopulmonary changes during sleep, attention has been shifting to changes in molecular mechanisms during sleep. In the late 1990s, the discovery of the molecular components that produce circadian clocks led to the study of circadian clock genes expression in many different organs.[60] Surprisingly, functioning clocks were found not only where they were expected—in the suprachiasmatic nucleus of the hypothalamus, the site of the master circadian clock—but in most organs. In particular, functioning clocks have been elucidated in the lung and cardiovascular system.[61,62] In cardiac myocytes and vascular smooth muscle cells, clocks are intrinsic to these cells since they maintain a circadian rhythm even when the cells are isolated and in culture.[62] Many other cell types have not been as extensively tested to date, but peripheral clocks including those in the liver, kidney, heart, and adipose tissue[63,64] have been described. These clocks likely alter the temporal pattern of expression of genes in the relevant organs. Microarray studies indicate that about 10% to 15% of all genes have diurnal variation in their expression levels. In the heart, for example, diurnal variation of genes promoting fatty acid oxidation occurs. Expression of these peaks in rats during the dark phase, that is, their active period.[62] Furthermore, the expression of K+ channel genes also exhibits diurnal variation in the heart and likely contributes to the altered excitability of the cardiac myocyte across the day.[61]

These observations indicate that at a fundamental molecular level, the heart and lung at night are not the same as during the day. Molecular processes in peripheral organs are also affected by sleep and sleep deprivation,[65] and this is an area that is likely to be a fruitful area of inquiry. Currently we do not know the mechanism mediating these changes. The molecular basis of circadian rhythms and molecular functions of sleep are discussed in more detail in Chapter 12.

CONCLUSION

There are major changes in cardiopulmonary function during sleep compared with wakefulness. These changes are specific to sleep state, with differences between NREM and REM sleep. The changes in cardiopulmonary function have important pathogenetic significance. These physiologic changes can contribute to the timing across the day of acute cardiovascular events; the periodic breathing that occurs during sleep at high altitude; the anatomic and neuronal changes that lead to obstructive apnea during sleep; and the pathogenesis of Cheyne–Stokes respiration. Currently, a new understanding of circadian variation in in cardiopulmonary function at the molecular level during sleep is evolving. New observations in this area will undoubtedly lead to new insights regarding cardiopulmonary physiology that will also have implications for the pathogenesis of disease and treatment.

CHAPTER 101

Differential Diagnosis and Evaluation of Sleepiness

Sritika Thapa
Mithu Sen
Meir Kryger

INTRODUCTION

Excessive daytime sleepiness (EDS) is a common problem affecting large segments of the general population. Although estimates depend on how sleepiness is defined (i.e., sleeping too much vs. falling asleep in the daytime), the National Sleep Foundation's annual Sleep in America poll in 2018 showed that among U.S. adults with excellent sleep health, 90% say that they feel effective at getting things done, while only 46% with poor health say they can get things done effectively; only 10% of American adults prioritize sleep over other daily activities like fitness/nutrition, work, social life, and hobbies.[1]

There is increasing evidence that sleepiness plays a part in both industrial and road traffic accidents and impaired performance. Sleepiness is most often caused by insufficient sleep or sleep disorders.

THE PHENOMENON OF SLEEPINESS

Sleepiness is both a subjective and an objective phenomenon, a constellation of sensations and a physiologic state with stereotypical behaviors. As such, it is sometimes difficult to define, and its measurement (see "Quantifying Sleepiness," below) depends on the circumstances. Sleepiness may be expressed as feeling sleepy, fatigued, or tired; sleeping too much; falling asleep inappropriately; or fighting to maintain alertness. Sleepiness can be reflected by any or all the following: heaviness of the eyelids, mild burning or itching of the eyes, difficulty keeping the eyes open, heaviness in the arms or legs, reluctance to move, loss of initiative, loss of interest in surroundings, and difficulty with concentration or memory. These sensations are accompanied by behavioral changes, such as rubbing the eyes, yawning and stretching, and nodding the head, and by generally reduced motor functions, such as speech, facial expression, and body movement. Sleep-deprived healthy individuals demonstrate attenuated facial expressions to stimuli.[2]

Sleepiness may also be considered a physiologic state like hunger or thirst. Just as hunger and thirst are physiologic states that occur with fasting and are satisfied by eating and drinking, sleepiness in individuals without a specific sleep disorder is produced by sleep restriction or deprivation and is reversed or satisfied by sleep. However, a difference between sleep and other physiologic factors is that, for example, while food may satisfy hunger, sleep quality and quantity are necessary to satiate sleep loss.

Sleep quality is impaired in individuals with specific sleep disorders, such as sleep apnea. The factors that produce and influence sleepiness are detailed below; they include such obvious factors as time since last asleep, previous amount of sleep, continuity of sleep, and normal 24-h circadian influences. Environmental stimuli influence this state and can determine, up to a point, whether this sleepy tendency will be manifested. For example, heavy meals, warm rooms, boring lectures, or monotonous tasks are usually considered soporific activities or situations. Under these circumstances, a person might feel sleepy and might fall asleep. However, the environmental factors themselves do not cause the sleepiness; they only allow it to be expressed. Equally, the same degree of physiologic sleep tendency might go unnoticed when environmental stimulation occurs in the form of a life-threatening situation. In other words, the degree to which sleepiness is experienced or evident in behavior is determined by the underlying physiologic sleep tendency (or the need for sleep) and environmental factors, which interact to manifest the sleep tendency or sleep propensity.[3]

While it is accepted that sleepiness is a physiologic state, the physiologic substrates of this state have not been identified. Neurotransmitters, such as serotonin, acetylcholine, histamine, and the catecholamines have been implicated in the sleep/wake mechanism along with a variety of other sleep-inducing substances, including adenosine through its inhibition of wakefulness-promoting neurons. While much research is ongoing, an understanding of the neurochemicals responsible for sleep, sleepiness, and loss of alertness is still evolving.[4–6]

QUANTIFYING SLEEPINESS

The sensation of sleepiness is often difficult to quantify, as are other subjective symptoms, such as pain or shortness of breath. All these subjective sensations may mean different things to different people and are modified by a variety of factors, including motivation, external stimulation, and competing needs. What constitutes extreme sleepiness for one person may be only mild sleepiness for another and depends on the situation in which it occurs. An approach is outlined in Table 101-1. Sleepiness has different dimensions, including feelings of perceived sleepiness, as well as self-estimates of sleepy behavior that are different in passive versus active situations. There exists the notion of a sleepiness trait, that is, a composite of sleep need and sleepability, which is the ability to transition into sleep rapidly.[7]

Other individual difference factors have been proposed to explain individual dissimilarities in sleepiness.[8] Sleep drive is an inherited trait.[3]

There have been initial efforts to identify gene variants associated with sleepiness using a genome-wide association study (GWAS).[9] It was conducted using data from the U.K. Biobank and based on one

question: "How likely are you to doze off or fall asleep during the daytime when you do not mean to (e.g., when working, reading, or driving)?" Subjects indicated the frequency of occurrence of this. Investigators were able to identify 42 genome-wide significant associations. Examining the association of these variants with objective data on sleep duration led to the proposal that there were variants associated with propensity to sleep (sleep drive) and others associated with sleep fragmentation.

■ Subjective Measures of Sleepiness

Subjective reports may be used to quantify sleepiness, but statements such as "I feel sleepy" and "I feel very sleepy" often do not distinguish between feelings caused by a high physiologic sleep tendency and those resulting from muscular fatigue, depressed mood, or a general lack of energy. Thus, several subjective sleepiness scales have been developed.

The *Stanford Sleepiness Scale* (SSS), the first to receive widespread use, is a seven-point self-rating scale ranging from 1 (alert, wide awake) to 7 (almost in reverie, sleep onset soon).[10] It is brief, is simple to use, and measures current degree of sleepiness. It has been shown to correlate with the performance of mental tasks and demonstrate changes in sleepiness with sleep loss. However, there are no normative data, and results often depend on the duration of prior sleepiness. For example, unlike normal persons who are experimentally sleep deprived, patients with more chronic sleep deprivation (e.g., sleep apnea) cannot be accurately tested with the SSS. Some patients who have an obvious overwhelming physiologic sleep tendency may claim to be only mildly sleepy yet fall asleep before your eyes. This was first observed in the early 1970s, and was a stimulus for one group of investigators to develop more objective measures of sleepiness.[10] Studies have shown that continued increases in lapses in performance occur over several days of sleep restriction, but the self-reported sleepiness does not continue to get worse.[11]

It is clear that over a period of months or years, many patients with sleep apnea lose their frame of reference with regard to normal alertness and cannot distinguish major changes in sleepiness. Thus, the subjective report of sleepiness (using the SSS) by people who are chronically and severely sleep deprived is not reliable.[10]

The *Karolinska Sleepiness Scale* (KSS) is a nine-point scale ranging from 1 (very alert) to 9 (very sleepy, fighting sleep, making an effort to keep awake), with verbal descriptions of every second point.[12] Like the SSS, the KSS requires the subject to integrate and translate a number of sensations to a continuum that is fairly abstract, despite the verbal descriptions. Ratings obtained with these scales may be affected by the situation in which the scale is presented (e.g., at rest or during performance of a task) and how the subject relates his or her perception to that particular time or place. The scales reflect current sleepiness. Nonetheless, both the SSS and KSS show high correlations with performance. The KSS was also found to be strongly related to EEG and electrooculographic signs of sleepiness.[12]

The *Epworth Sleepiness Scale* (ESS; Table 101-2) was designed to measure sleep propensity in a single, standardized way and is based on questions relating to eight situations, some known to be very soporific.[13] The ESS, in contrast to the KSS and SSS, assesses symptoms of chronic sleep deprivation. The questions are self-administered, and subjects are asked to rate on a 0 to 3 scale how likely they are to doze off in the situation based on their usual habits over recent weeks to months. The ESS tries to overcome the fact that people have different daily routines, some facilitating and others preventing daytime sleep. An ESS of 10 or below is considered normal. Scores above this are considered indicative of excessive sleepiness. ESS scores have shown significant correlations with mean sleep latency in the multiple sleep latency test (MSLT, see further below) and have distinguished groups of patients with disorders of excessive sleepiness such as narcolepsy, OSA, and idiopathic hypersomnolence. The ESS score has been validated against the MSLT in a patient population with sleep disorders, specifically patients with narcolepsy, and shows 95% sensitivity and 73% specificity in comparison to the MSLT.[14] The ESS has high test–retest reliability and a high level of internal reliability in normals and patients with sleep apnea.[15] There are different dimensions to the symptoms of sleepiness. Thorarinsdottir et al. have shown that in the general population there are individuals with elevated Epworth Sleepiness Scores who do not complain of sleepiness, while there are others with normal Epworth Sleepiness Scores who complain of sleepiness on multiple days/week.[16]

■ Objective Measures of Sleepiness

The Multiple Sleep Latency Test (MSLT) has been developed and standardized as an objective, reliable, and reproducible measure of physiologic sleep tendency.[10] Performed at intervals throughout the day, the MSLT measures the time to sleep onset, as determined by the EEG. The test is based on the assumption that, given the proper surroundings, physiologic sleep tendency will be expressed by going to sleep; its appeal is intuitive in that if one patient is more sleepy than the other, the sleepier patient should fall asleep more quickly.

Patients are instrumented to record the EEG, electrooculogram (EOG), and electromyogram (EMG); they are put in a quiet, darkened, temperature-controlled room and are asked to lie quietly, close their eyes, and try to fall asleep. Naps are scheduled at 2-h intervals, with 20 min allowed for sleep to occur. If an individual initiates sleep, a mean sleep onset latency (SOL) can be measured and can support excessive daytime somnolence or a diagnosis of narcolepsy, as explained below. Thus, the average SOL of the naps represents the result of the MSLT. Both clinical and research protocols exist for conducting the MSLT.[14]

Since sleepiness follows a circadian rhythm (see "Circadian Rhythms," below), one nap is insufficient to document and quantify daytime sleepiness. Accordingly, a minimum of four and a maximum of six naps are recommended. However, pooled data from normal persons of wide age range showed a statistically significant difference in mean sleep latency with 4 or 5 naps (10.4 ± 4.3 min vs. 11.6 ± 5.2 min, respectively), while pooled reports from narcolepsy patients showed the mean sleep latency was 3.1 ± 2.9.[17] The MSLT is a reliable, reproducible test that has been validated in a number of sleep deprivation experiments in normal subjects and in a variety of clinical conditions with patients who have disorders such as narcolepsy and sleep apnea; it may be useful for documenting treatment response to a sleep disorder, such as medications in narcolepsy or CPAP in sleep apnea.

An important advantage of the MSLT is that patient motivation cannot counteract the effects of previous sleep loss on sleep latency. That is, while most people can be motivated to compensate for reduced performance after sleep deprivation, motivation cannot overcome an increased pressure for sleep, particularly when the patient is in bed in a darkened room. A mean SOL of ≤8 min is considered pathologic sleepiness. Any sleep-onset REM (SOREM) is closely observed, as it can signify a diagnosis of narcolepsy. Two or more SOREMs during the nap opportunities support a diagnosis of narcolepsy (see below).[18] Early REM on the proceeding PSG also can be considered a SOREM supporting the diagnosis of narcolepsy.

The Maintenance of Wakefulness Test (MWT) is an alternative to the MSLT. This is a variation on a theme in which subjects sit in a chair in a darkened room and are requested to remain awake for 20 (or 40) min. The test was developed on the assumption that the ability to fall asleep and the ability to stay awake are two separate phenomena. The MWT has undergone further tests of validity but has been criticized for lack of a standardized protocol, with 20-, 30-, and 40-min tests being reported. Recent practice parameters suggest

TABLE 101-2 Epworth Sleepiness Scale

Epworth Sleepiness Scale

Name: ______________________ Today's date: ______________

Your age (Years): __________ Your sex (Male = M, Female = F): __________

How likely are you to doze off or fall asleep in the following situations, in contrast to feeling just tired?

This refers to your usual way of life in recent times.

Even if you haven't done some of these things recently try to work out how they would have affected you.

Use the following scale to choose the **most appropriate number** for each situation:

0 = **would never** doze
1 = **slight chance** of dozing
2 = **moderate chance** of dozing
3 = **high chance** of dozing

It is important that you answer each question as best you can.

Situation	**Chance of Dozing (0–3)**
Sitting and reading	
Watching TV	
Sitting, inactive in a public place (e.g., a theatre or a meeting)	
As a passenger in a car for an hour without a break	
Lying down to rest in the afternoon when circumstances permit	
Sitting and talking to someone	
Sitting quietly after a lunch without alcohol	
In a car, while stopped for a few minutes in the traffic	

THANK YOU FOR YOUR COOPERATION

that a 40-min protocol may be better than a 20-min protocol, as this is more challenging and identifies patients with real difficulty staying awake due to the longer duration of the test.[17] This is a relevant evaluation when assessing whether a patient can stay awake in a situation of personal or public safety.

While both MSLT and MWT require observer recognition of EEG changes, quantitative computerized analysis *of EEG* has been proposed as an alternate and perhaps more sensitive objective measure of sleepiness. Increased EEG delta activity with sleep deprivation and decreased alpha activity just before sleep onset are two possible metrics. However, these have yet to be translated into clinically useful tests. The Alpha Attenuation Test (AAT) has been validated in sleep-restricted normals and in patients with narcolepsy and correlates strongly with the MSLT.[14]

The *Oxford Sleep Resistance Test* (OSLER test) was designed as a low-cost alternative designed to reproduce many of the features of the MWT, but without the labor-intensive, continuous monitoring of EEG.[19]

In the OSLER test, subjects respond to a visual stimulus. A light-emitting diode mounted on the wall flashes for 1 s every 3 s in fixed intervals. If there is no response after seven consecutive stimuli, the subject is deemed to be asleep and the test is ended. The original study compared OSLER sleep latency with MWT latency in 10 patients with OSA and 10 control subjects done on separate days and showed that OSLER could be validated against the MWT in this patient population. Two other studies involving small numbers of patients in a sleep disorder center and/or normal subjects before and after sleep deprivation have demonstrated excellent agreement between the two measures and suggest that the OSLER could be an alternative to measuring sleepiness.[20] There are no large-scale studies using the OSLER; the main limitation of this test is its dependence on patient cooperation.[21,22]

One disadvantage of these tests is that it requires a whole day of testing. This has limited their widespread application.

■ Performance and Vigilance Tests

Measurements of performance after sleep loss reflect daytime sleepiness, since most people report decreased performance after a sleepless night. Previously it was felt that only performance tests that were prolonged and monotonous were sensitive to sleep loss.

However, the work of Dinges et al. (using his Psychomotor Vigilance Task [PVT]) demonstrates that if the signal rate is high and the response measure sufficiently sensitive, repetitive tasks of only 10 min duration will expose the limits of performance in sleepy persons.[23] Recently shortened versions of this test, that is, 3 min, have been applied.[24] Performance decrements resulting from sleep deprivation (or sleep disorders such as sleep apnea) can be observed with such a task if results are analyzed over time. This time-on-task or vigilance decrement may be observed as evidence of fatigue even in well-motivated subjects with adequate prior sleep, and it manifests itself as a decline in performance as time-on-task increases.

When the subject is sleep-deprived, it is impossible to sustain attention long enough to maintain peak performance throughout the entire task, and lapses in performance occur. Sleep loss increases the rate of decline in performance. The number of interrupted episodes also contributes to performance decline. The Psychomotor Vigilance Test (PVT) has become the most widely used measure of neurobehavioral performance. It has been validated with the SSS and MSLT. The test has demonstrated consistent individual differences in neurobehavioral deficits from sleep loss when repeated in the same subject, which indicate differential trait vulnerability to sleepiness.[25] Studies in monozygotic and dizygotic twins indicate that it is a very heritable trait.[3]

While the MSLT and MWT can provide helpful information, they require repeated testing every 2 h and a whole day of tests. A single administration of objective tests, in particular the PVT, can help assess sleepiness in controlled conditions that may be applied clinically.[26]

Other tests of sustained attention and performance have been developed, many to assess simulated driving performance. Using a divided attention task, in which individuals are required to pay attention to more than one aspect of the task, such as a driving task, patients with sleep apnea have been shown to perform poorly; in some cases, performance is equal to or worse than normals impaired by alcohol.[27] Nonetheless, sleepiness, as measured by MSLT, accounts for less than 25% of the variance in tracking performance. Thus, while the effects of sleepiness on performance may occur in a dose-dependent fashion in normals, performance decrements in patients who are sleepy because of an underlying sleep disorder may be accounted for by factors other than sleepiness.

Mitigating subjective “sleepiness” in patients with mild to moderate OSA, untreated with CPAP, has been shown with modafinil. The effect size was clinically important, as was the improvement on the driving simulator performance and reaction time.[28]

FACTORS AFFECTING SLEEPINESS

Sleepiness is determined by the quantity of sleep and the quality and type of sleep, interacting with circadian rhythms or drugs that patients may be taking.

■ Sleep Quantity

The amount of nocturnal sleep has a strong relationship to the degree of daytime sleepiness. A “normal” sleep duration is typically in the range of 7 to 8 h.[29] Partial or total sleep deprivation is followed by increased daytime sleepiness in normal persons. Furthermore, sleep restriction will become cumulative over time and lead to increasing daytime sleepiness.[23]

The effect of sleep restriction on sleep onset latency (SOL) is shown in Fig. 101-1. When the sleep of young adults was reduced by 2 h a night on consecutive nights, sleepiness (as measured by the MSLT) progressively increased over 7 days. Even as little as 1 h per night of sleep loss will accumulate over time and lead to daytime sleepiness—a fact generally not appreciated. Each person has a certain biologic sleep need, and the specific amount varies from one subject to the next. Regardless of cultural or environmental factors, most adults sleep 7 to 8 h per day, but the old adage that we must sleep 8 h each night is not true for everyone. Some people require more than 8 h, and others less.

There may be many contributors to the amount of sleep an individual requires, including a genetic contribution.[30,31] Gene variants associated with sleep duration have been identified using genome-wide association studies (GWAS) with both self-reported sleep durations and sleep duration estimated from accelerometry data.[32–34] In the absence of pathology, normal human sleep length varies between 6 and 9 h, although some people require less. It would be ideal to require a minimum amount of sleep to allow maximum productivity in work and adequate time for social pursuits. Indeed, some investigators believe that Western society predisposes to sleep deprivation[35] while others argue that this is not the case and the situation is more complex.[36] With economic and social constraints—the latter leading to voluntary sleep restriction—the sleep period is the time most encroached upon, potentially leading to daytime sleepiness.[37] Data from the American Time Use Survey (ATUS) show that work time, time for commuting, and time for socializing and leisure are the main determinants of sleep duration.[37]

There has been progressive reduction in sleep duration over many age ranges in the United States. There are multiple etiologies for this, including work intruding into sleep period. Overall, it appears short sleep duration is increasing in prevalence, which is associated with adverse health outcomes, such as weight gain and associated morbidities of obesity.[38] In addition, the prevalence of short sleep (<6 h) has increased in individuals who are employed full time.[31]

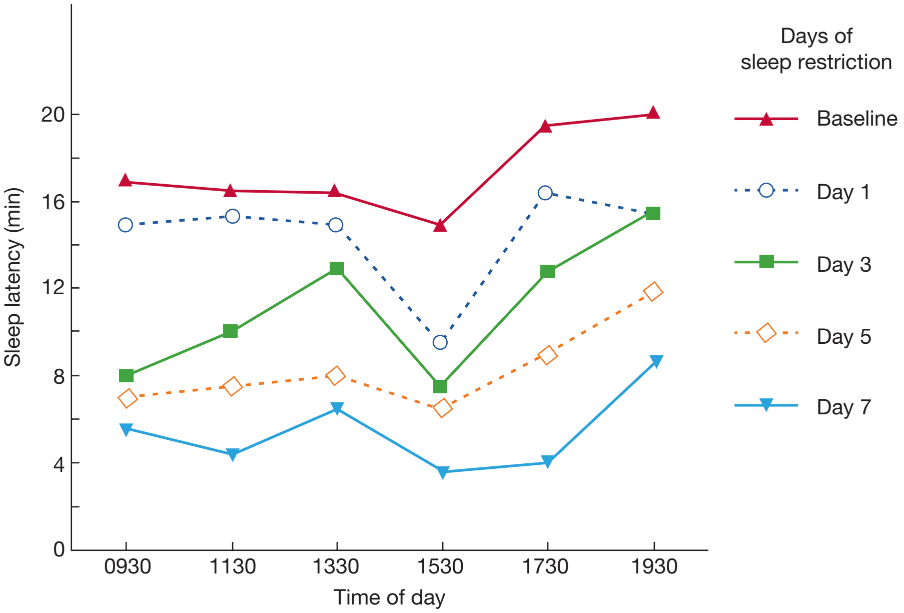

Figure 101-1 Average daily sleep latency test scores for young adults when nighttime sleep was reduced by 2 hours a night for 7 consecutive nights. *(Adapted with permission from Dement WC, Carskadon MA. An essay on sleepiness, in Boldy-Moulinier M (ed). Actualitiés en Médécine Expérimentale, en Hommage au Prof D Passouant. Montpellier, Euromed; 1981.)*

Voluntary sleep restriction or insufficient sleep causes daytime sleepiness. Among all prominent features differentiating the group of patients with insufficient sleep from those with narcolepsy is the report, obtained from the sleep history, of a disparity between the amount of sleep on weekdays and that on weekends. People with insufficient sleep typically have a much longer sleep period on weekends (by 2 h or more), often called "catch-up" sleep.

Most patients consider their weekly sleep loss trivial and assume that it is recovered on weekends. However, while recovery from a single experimental sleep restriction occurs in a couple of nights, it is not likely that repeated episodes of sleep deprivation can be compensated for in just one night. A study of a large group of normal subjects without complaints of daytime sleepiness has shown that young subjects (particularly college students) had shorter sleep latencies than did older subjects. Within the group of 120 young subjects, 12 healthy, nonsmoking men aged 21 to 35 years had a mean sleep latency of less than 6 min on MSLT testing, whereas another 12 had an MSLT of greater than 16 min.[14] These subjects had baseline testing and then extended their sleep period time from 8 to 10 h over 6 days. Repeat testing on days 1, 3, and 6 showed stepwise increases in MSLT and performance testing for both subgroups. The data support the notion that chronic voluntary sleep restriction in real life produces objective sleepiness that may or may not be perceived by the subject.

Sleep Quality

Sleep quality is perceived to be abnormal when sleep is decreased or discontinuous. Disrupting sleep continuity—that is, causing arousal from sleep, either experimentally or by sleep disorders—affects the quality of sleep and results in increased physiologic sleep tendency. An arousal can be defined as a brief (3–15 s) speeding up of the EEG, or as a burst of alpha activity occasionally accompanied by transient increases in skeletal muscle tone. These typically do not result in awakening as defined by standard sleep staging criteria or behavioral indicators.

Sleep studies can identify various causes of arousal, such as recurrent obstructive apnea, periodic leg movements, or chronic pain, in some but not all cases. A common exception is the patient with chronic obstructive pulmonary disease (COPD) who has frequent arousals from sleep in the absence of obstructive apnea or leg movements.[39] Patients with COPD often experience oxygen desaturation during sleep, and this is a potential stimulus for arousal. Nonetheless, compared with age-matched controls, patients with COPD have discontinuous sleep and poor sleep efficiency (defined as percentage of time actually asleep as a fraction of total time in bed).

Auditory stimuli presented externally to normal subjects during sleep can produce arousal; repetitive presentation of such stimuli can produce daytime sleepiness. Several studies have shown decreased performance and increased sleepiness the day after repetitive arousal, with the degree of daytime sleepiness related to the frequency of nocturnal sleep disruption. Not surprisingly, the shortest sleep latency occurred after the most fragmented nocturnal sleep. This increased sleepiness will result even if the stimulus is only sufficient to produce EEG signs of arousal, without full wakefulness. The importance of sleep disturbance from environmental noise has been reported by Basner et al.[40] There are both auditory effects such as EEG arousals, and impaired daytime alertness from lack of sleep quality and quantity that affect quality of life. There are other nonauditory effects, such as increased catecholamine release and association with cardiovascular disease. Environmental noise exposure, such as from airports and other urban environmental areas, can cause lasting damage resulting in hearing loss. Noise-induced hearing loss and tinnitus may not always be recognized in our society, but the effects on affected individuals' quality of life can be tremendous.

New metrics have been introduced to measure sleep quality. These are derived from data collected during the overnight sleep study. They provide continuous measure of sleep depth. The first measure is odds ratio product (ORP) that is derived from spectral analysis of the EEG signal.[41,42] The second is derived from the ECG and is called cardiopulmonary coupling.[43]

Circadian Rhythms

If sleep latency is measured every 2 h over a complete 24-h day, a biphasic pattern of sleep tendency becomes obvious (Fig. 101-2). This demonstrates that there are two peaks and troughs of sleepiness over a 24-h period. Not surprisingly, the times of increased sleepiness are during the nocturnal hours and during the daytime hours (in the midafternoon between 2 and 4 PM, i.e., siesta time). This circadian rhythm of sleepiness is present in all age groups, although the time of the peak rhythm may vary. This biphasic rhythm of sleepiness across the day is reflected in time of occurrence of car crashes attributed to the driver falling asleep at the wheel.[44] The circadian rhythm of sleepiness is similar to other circadian rhythms in that it possesses an endogenous periodicity that can be affected by environmental influences that fine tune or entrain the rhythm. Even in the absence of these environmental cues (i.e., awakening time, alarm clock, degree of light or darkness, food and stimulants, and social contact), rhythms show a persistent periodicity.

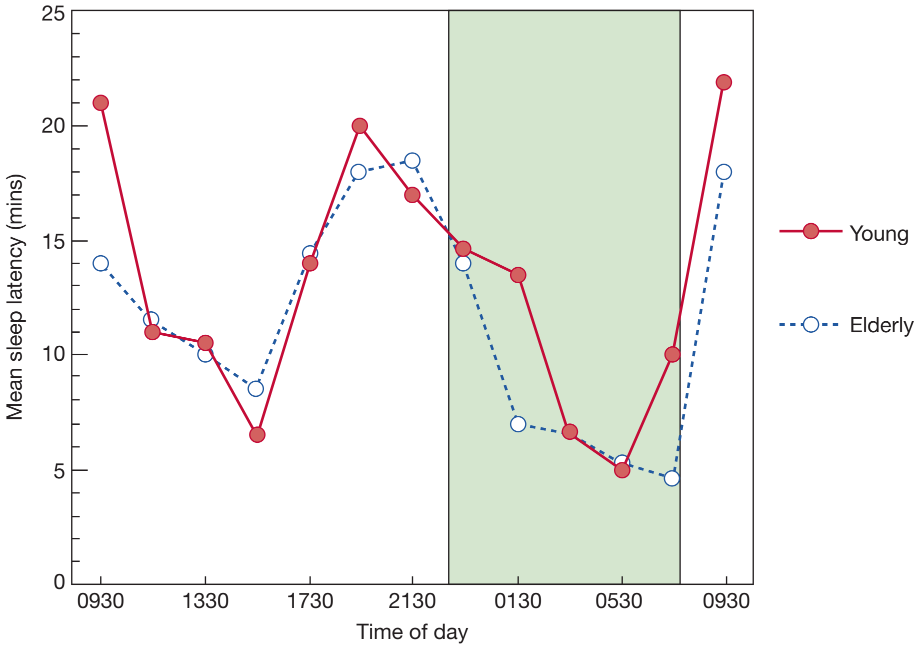

Figure 101-2 Sleep latency (mean) as a function of time of day for young subjects *(filled circles)* and elderly subjects *(open circles)*. *Stippled area* denotes nighttime sleep period. *(Adapted with permission from Richardson GS, Carskadon MA, Orav EJ, et al. Circadian variation of sleep tendency in elderly and young adult subjects. Sleep. 1982;5(Suppl 2):S82–S94.)*

The circadian rhythm of temperature is extremely stable. Temperatures falls in the late afternoon, are lowest during the middle of the sleep period, and rise before morning awakening. The temperature rhythm synchronizes most closely with sleepiness. Although the amplitude of body temperature and sleep latency rhythms differs considerably, no other biologic rhythms correlate so well in time. Circadian rhythm is discussed more extensively in Chapter 12.

Two other examples of the influence of circadian rhythms on sleepiness are obvious. The first is that associated with shift work, and the second is due to transcontinental travel (jet lag). Workers with a normal nocturnal sleep period and a previously stable circadian sleepiness rhythm suddenly will have a trough of sleepiness during the middle of their night work period. They will attempt to stay awake, while the circadian influences are promoting sleep.[45] Jet lag is similar, in that the body's circadian rhythm is out of synchrony with the clock time. As a result, performance may suffer. These differences are the result of trying to sleep at times that the clock is signaling wakefulness and is generating an arousal signal. Sleeping at inappropriate times impairs sleep efficiency (i.e., amount of sleep/time in bed) and sleep quality.

■ Medications

Drug effects on sleep can be significant and can either promote sleep and sleepiness or increase wakefulness and alertness. When assessing subjective or objective sleepiness, it is important to know whether the patient is taking a medication that may affect the degree of sleepiness, that is, the sleepiness may be a side effect of their medication.

Not surprisingly, sedative drugs increase sleepiness. Benzodiazepine hypnotics have been used to help people get to sleep at night; however, nonbenzodiazepine hypnotics also are used. Many objective studies confirm the ability of hypnotics to shorten sleep latency at bedtime through GABA_A receptor stimulation. When given during the day, they promote sleep. However, the daytime carryover effect of nocturnal sedation is not always recognized. This effect occurs most commonly with long-acting benzodiazepines, but it may occur with other medications as well. Recently, warnings have been issued from the FDA about potential sleepiness the morning after taking these medications, especially in women, and have recommended reduction in zolpidem dosages to half to increase patient safety. Second-generation antiepileptics (i.e., gabapentin, pregabalin, vigabatrin) also act as GABA agonists without interacting with the GABA_A or GABA_B receptors. Alcohol consistently shortens sleep onset and produces sedation, whether given at night or during the day. However, it also alters sleep architecture by suppressing REM sleep and contributing to sleep fragmentation through the latter portions of the night.[46]

Drugs that produce sleepiness include antihistamines, which are used in allergy and pulmonary practice. Many of the early H_1 antihistamines, such as diphenhydramine and chlorpheniramine, have been shown to reduce the MSLT. Some antihistamines, such as terfenadine and astemizole, do not produce objective sleepiness. The more lipid-soluble drugs (e.g., diphenhydramine and chlorpheniramine) penetrate the central nervous system more easily and, therefore, are more likely than less lipid-soluble drugs to produce sedation. Other medications with high lipid solubility have been reported to produce daytime sedation; the most common of these are the beta-blocker drugs. There are no controlled, objective studies of sleep latency with this type of drug, and sleepiness from these medications is based on reports of side effects or subjective questionnaires, such as the Pittsburg Sleep Quality Index (PSQI).[47]

The effect of a particular drug in producing sleepiness also depends on the background level of sleepiness or alertness. When ethanol or caffeine is given to normal-sleeping young men in the morning, one might expect ethanol to produce daytime sleepiness and caffeine to increase sleep latency during the day. Subjects are consistently sleepier after ethanol than after caffeine ingestion, but fully rested subjects (those having spent 11 h in bed) do not show sleepiness after taking ethanol. In other words, the sedative effects of drugs such as alcohol can be enhanced by increased background sleepiness. Thus, a driver who is sleepy to start with may be as vulnerable after just one or two drinks as a previously alert driver who has become legally intoxicated.[46]

Drugs that increase wakefulness or alertness include stimulants such as amphetamine, methylphenidate, modafinil, and armodafinil. These drugs are most often used in the treatment of narcolepsy but may be used to stay awake for long periods of time. Caffeine, probably the most widely used stimulant, can reduce daytime sleepiness and transiently increase alertness. Excessive caffeine intake paradoxically may also cause a degree of daytime sleepiness. This occurs when caffeine levels persist into nocturnal hours and promote difficulties with sleep onset and increased awakenings during sleep.

PREVALENCE OF EXCESSIVE DAYTIME SLEEPINESS

Prevalence rates for sleepiness depend greatly on the type of questions addressing sleepiness. For example, "Are you sleeping too much," "Are you falling asleep during the daytime," and "Does your sense of sleepiness impair your daytime activities?" all result in widely different prevalence rates. Also, men tend to report sleepy behavior whereas women report feelings of EDS, again contributing to variable prevalence. Prevalence of sleepiness also varies with the population examined.

There are many socioeconomic and demographic factors that may contribute to sleep disorders or poor sleep quality or quantity in the population. Specific associations with long SOL include being female, having black/African-American heritage, lower education level, lack of private health insurance, and food insecurity. The demographics are most associated not only with prolonged SOL, but also with nonrestorative sleep and sleep maintenance difficulties, including early morning awakenings. EDS occurs more frequently with female sex and in divorced individuals.[48]

By far, the most common sleep disorder causing excessive daytime sleepiness in sleep clinics is obstructive sleep apnea. The prevalence is 10% (95% confidence interval [CI], 7–12) among 30- to 49-year-old men, 17% (95% CI, 15–21) among 50- to 70-year-old men, 3% (95% CI, 2–4) among 30- to 49-year-old women, and 9% (95% CI, 7–11) among 50- to 70-year-old women.[49]

There are data showing that OSA is a heterogeneous disorder, including from a symptomatic point of view. Cluster analysis of responses to a comprehensive questionnaire of patients in the Icelandic Sleep Apnea Cohort (ISAC) found that there were three distinct subtypes of patients: (1) disturbed sleep, where major complaints were initiating and maintaining sleep (insomnia); (2) relatively asymptomatic; and (3) excessively sleepy.[50] The first two groups had an average or normal Epworth Sleepiness Score <10. The excessively sleepy group had marked sleepiness with an average Epworth Sleepiness Score of 15.6, and a large proportion fell asleep driving, that is, they were a very sleepy group of subjects. The existence of these subtypes has now been replicated in multiple studies: (1) in studies with data from multiple sleep centers worldwide that are part of the Sleep Apnea Global Interdisciplinary Consortium;[51] (2) in a population-based cohort in South Korea;[52] (3) in the Sleep Heart Health Study, a population-based cohort;[53] (4) in patents with OSA who are part of the recruitment by the Canadian National Network for Sleep and Circadian Disorders;[54] (5) the Hispanic Cohort study in the United States;[55] and (6) a clinical cohort of patients with OSA from Chile.[56] While in these studies the basic three subtypes were present, the optimal cluster solution varied between three and five subtypes. For example, in the Sleep Heart Health Study there was an additional subtype with moderate sleepiness.[53] While the same subtypes were present in both clinical cohorts and in population studies, the frequency of the different subtypes varied with a higher proportion of asymptomatic in the general population. These subtypes vary not only in symptoms but also in risk for cardiovascular disease.

Analysis of data from the Sleep Heart Health Study showed that it is only the excessively sleepy subtype that has an increased risk of CV events; the other subtypes do not.[53] This result has been confirmed in analysis of the data from the clinical cohort from Chile.[56]

This is an important result since it provides a potential explanation as to why recent randomized controlled trials (RCTs) for effect of CPAP on cardiovascular events were negative,[57–59] contrasting with findings from previous epidemiologic studies.[60] These RCTs excluded excessively sleepy individuals for ethical reasons.[61]

EVALUATING THE SLEEPY PATIENT

Keeping in mind the factors that determine daytime sleepiness, the sleep history can be individualized and can be very helpful in narrowing the differential diagnosis (Table 101-3).

One should always question the patient about his or her nocturnal sleep, looking specifically at sleep onset time, sleep period time, number of awakenings, and time of rising in the morning. One should also ask about when the change in sleep occurred as well as questions about sleep hygiene (e.g., when awake, reading book in dim light vs. playing games on an electronic device with bright light). Sleep onset phenomena such as sleep paralysis and hypnagogic hallucinations often suggest a diagnosis of narcolepsy, although these sometimes occur in apneics who are severely sleep deprived.[17] A history of loud snoring or stopping breathing during sleep is suggestive of sleep apnea hypopnea syndrome, particularly if the snoring is "cyclical" rather than continuous, with periods of loud snoring or snorting alternating with quiet intervals. Since insufficient sleep may be the cause of sleepiness, it is important to ask if there is any difference in the amount of sleep required during the week compared with that on weekends. Equally important is whether the patient has any changes in subjective sleepiness on weekends or holidays compared with weekdays.

In some instances, more information will be obtained from the spouse (or bed partner) or from a sleep/wake diary, since not all people are aware of the severity of their sleepiness. Moreover, patients may not understand the importance of good sleep hygiene; the diary can serve as a reminder for patients to be diligent about it.

In estimating the degree of daytime sleepiness, it is useful to ask when and during what activities the patient experiences sleepiness. Is the patient sleepy on awakening in the morning, or is it only by midday? Does the patient fall asleep while doing things or only when inactive? Driving to and from work are important times when sleepiness may become obvious, particularly while the person is waiting at a railroad crossing or stoplight. This is particularly relevant to shift workers who fall asleep on the drive home from work after their night shift. Episodes of automatic behavior, related to "microsleeps," often occur while one is driving. Do patients nap during the day, and if so, is the nap refreshing? Many patients with sleep apnea are still sleepy or foggy after a nap, whereas patients with narcolepsy most often feel refreshed immediately upon awakening after a nap.

TABLE 101-3 Common Causes of Persistent Daytime Sleepiness

Obstructive sleep apnea and other sleep-disordered breathing conditions (e.g., neuromuscular weakness with nocturnal respiratory failure)
Narcolepsy/cataplexy syndrome
Sleep-related movement disorders (periodic limb movement disorder, bruxism, etc.)
Depression
Postviral fatigue
Head injury
Metabolic, toxic, and drug-induced hypersomnolence
Idiopathic hypersomnolence
Insufficient sleep
Circadian rhythm sleep disorders

Since drugs can have a profound effect on sleep and sleepiness, a careful drug history is mandatory in the assessment of sleepiness. The clinician must remember to include queries not only about drugs that specifically affect sleep (hypnotics, sedatives, or other psychoactive medications) but also about substances that may not be considered to have any effect on sleep or waking. In particular, alcohol is a known precipitant or exaggerating factor for sleep apnea; patients often report that they feel much worse the day after ingesting alcohol despite having had a nonintoxicating dose.[62]

Apart from a general physical examination, one should pay particular attention to obesity and the size of the jaw, face, and upper airway, looking for obvious skeletal abnormalities—particularly retrognathia or micrognathia. One should carefully examine the upper airway, looking for nasal obstructions, such as a deviated nasal septum or inflammatory allergic polyps. In addition, the oropharynx should be examined, looking at the size of the tongue, the position of the soft palate, and the size of the uvula. Finally, the larynx should be assessed to rule out upper airway tumors or other obstructing lesions. While the typical patient with sleep apnea patient is an obese, plethoric man with a thick neck, it is important to remember that examination of the awake, upright airway may bear no relationship to what happens when the patient is supine and asleep. Thus, the diagnosis of sleep apnea usually is confirmed by nocturnal polysomnography or a more limited home study (Chapter 98).

The patient who has a history of snoring and daytime sleepiness but has no flow limitation, or sleep apnea or hypopnea during his or her nocturnal study, should undergo an objective measure of daytime sleepiness, because some patients who claim to have substantial daytime somnolence are simply looking for compensation.[63] Also, some patients with OSA remain sleepy despite adequate treatment of their apnea; an additional sleep disorder may coexist. There may also be residual sleepiness in patients with mild to moderate OSA despite CPAP treatment (see below). Again, daytime quantification of sleepiness will be necessary. The only disadvantage of the MSLT is that it is an inefficient test. Compared with objective measurements of airflow (e.g., FEV$_1$), which take seconds to perform and interpret, the MSLT takes almost a whole day and provides only one piece of information. Until better tests are developed and validated, however, the MSLT will continue as a standard, albeit time-inefficient, objective measure of daytime sleepiness. There are efforts to develop blood tests, that is, biomarkers, for sleepiness.[64]

It is important to remember that CNS pathology can independently contribute to EDS. While the central hypersomnias fall within the realm of sleep medicine (see below), in other neurologic diseases (e.g., Parkinson disease) or neuromuscular diseases (e.g., myotonic dystrophy), EDS can be a presenting symptom that the pulmonologist should keep in the differential diagnosis.

■ Central Hypersomnias

As mentioned above, EDS is usually associated with insufficient sleep (the most common cause, as 35.2% of American adults sleep <7 h),[65] circadian rhythm disorders, disturbed nocturnal sleep from sleep-related breathing disorders, medical or psychological disorders, or medications. Central disorders causing hypersomnolence can be diagnosed once all these conditions have been excluded. The International Classification of Sleep disorder, 3rd edition (ICSD-3), divides central disorders of hypersomnolence into eight categories (Table 101-4).

Narcolepsy type 1 (NT1) or narcolepsy with cataplexy (as previously known) is a chronic neurologic disorder with a prevalence of 0.025% to 0.05% worldwide. There is a known association with HLA

TABLE 101-4 Central Disorders of Hypersomnolence

Narcolepsy type 1
Narcolepsy type 2
Idiopathic hypersomnia
Kleine-Levin syndrome
Hypersomnia due to a medical disorder
Hypersomnia due to a medication or substance
Hypersomnia associated with a psychiatric disorder
Insufficient sleep syndrome

Data from Judd BG, Sateia MJ: The International Classification of Sleep disorder, 3rd ed. Rochester, MN: AASM; 2014.

DQB1*0602, making gene–environment interaction likely as the etiologic factor.[66] The proposed mechanism is loss of hypothalamic hypocretin-producing neurons in genetically predisposed individuals, enhanced by environmental factors such as infections or vaccines, suggesting autoimmune mechanisms.[67,68] Hypocretin (orexin) stabilizes wakefulness and sleep through modulation of other neurotransmitters; thus the disturbance in the sleep-wake system due to its deficiency leads to a dissociated state with REM intrusions into wakefulness.[68,69]

The classic tetrad for narcolepsy is EDS, cataplexy, sleep paralysis, and hallucinations. The latter occur at sleep onset (hypnagogic) or sleep offset (hypnopompic). However, only <10% present with all four symptoms, adding to the delay in diagnosis while cataplexy is present in only 65% to 75% of individuals with NT1.[70]

Cataplexy is a very specific symptom of NT1, characterized by sudden, brief loss of muscle tone (<2 min) triggered by strong, mostly positive emotions with preserved consciousness, in particular laughter. Sturzenegger et al. showed that specific questions on severity of EDS and characterization of cataplexy helped in recognizing subgroups of narcoleptics and their differentiation from nonnarcoleptic EDS patients or reporting cataplexy-like episodes.[71] Sagging of the jaw and/or trembling of the knees are the most common localizations during cataplexy, which, along with positive emotions, are more common triggers in cataplexy than cataplexy-like episodes.[71]

Sleep paralysis and hallucinations are less specific symptoms that may be present in other central sleep disorders as well. Sleep paralysis also occurs with sleep deprivation in normals, with a prevalence rate of 7.6% in the general population, and even higher rates in students (28.3%) and psychiatric patients (31.9%).[72] In addition to the classic tetrad, disturbed nocturnal sleep, mood disorders, other sleep disorders like REM behavior disorder (RBD; especially in young patients), periodic limb movements during sleep, and OSA can be associated with narcolepsy.[69]

The Ullanlinna Narcolepsy Scale (UNS) and Swiss Narcolepsy Scale (SNS) are instruments used to screen for narcolepsy with cataplexy if a patient's ESS score is >10. In addition to subjective complain of EDS, NT1 may be diagnosed by the clear presence of cataplexy and a Multiple Sleep Latency Test (MSLT) showing a mean sleep latency ≤8 min and two or more SOREMPs (one SOREMP can be replaced with a REM within 15 min of sleep onset on the preceding PSG) or cerebrospinal fluid (CSF) hypocretin-1 deficiency (<110 pg/mL or <1/3 of the mean values of normal subject with the same assay).[73] Since MSLTs may show similar findings in sleep deprivations, shift work, or secondary hypersomnia, a 2-week actigraphy or sleep log should be maintained, along with stoppage of interfering drugs (stimulants and REM-suppressing) 2 weeks prior to the MSLT.

Drakatos et al.[74,75] have suggested that REM arising directly from N1 or wake phase instead of N2 or N3 (either during MSLT or during PSG during the first REM period) increases the likelihood of NT1. This pattern of REM transition is completely absent in idiopathic hypersomnia and occurs intermediately in narcolepsy type 2; it is also associated with a worse therapeutic response.[69,74,75] HLA typing has limited use, as 20% to 30% of the general population also carries the HLA DQB1*0602 gene; thus, only its absence would help to support an alternate diagnosis.[69]

Efforts have been made to identify narcolepsy from overnight sleep recordings, for example, PSGs. Investigators used a neural network to develop a plot across the whole sleep study of the probability of different sleep stages and wakefulness (e.g., see Fig. 101-1). There was a distinct difference between normals and individuals with narcolepsy (Fig. 101-3). In narcolepsy, there was an admixture of predictions of different states at the same timepoint (Fig. 101-3).[64]

In *narcolepsy type 2* (NT2), like NT1, there is EDS and REM sleep dysregulation, but there is no cataplexy, and CSF hypocretin-1 levels are not low. NT2 is thought to be caused by localized loss of hypocretin cells, which is less severe compared with the 90% loss of hypocretin neurons in NT1.[76] While 90% of NT1 patients show low hypocretin levels, only 10% to 30% of patients with NT2 have low

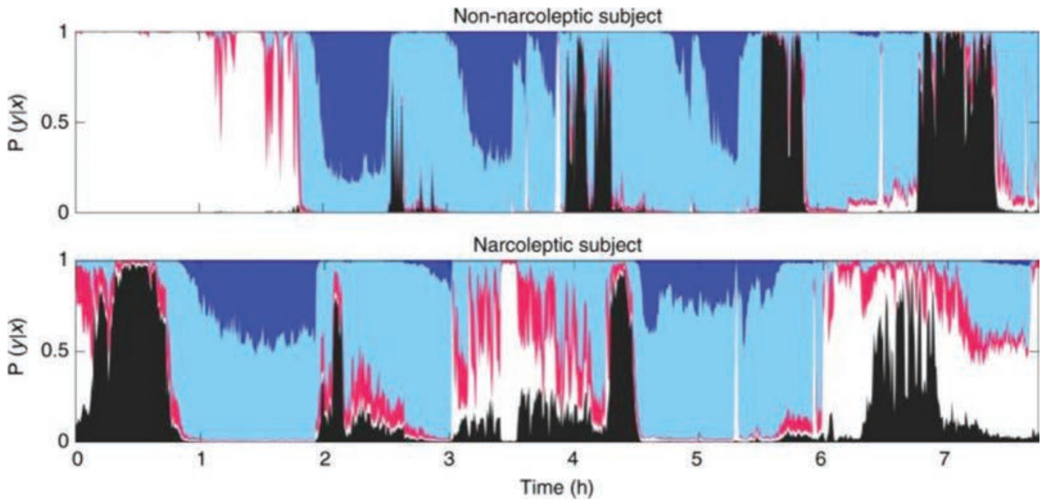

Figure 101-3 Examples of plots of probability of different sleep stages *(y axis)* and wakefulness during a full sleep study. The plot in the *top panel* is for a normal subject, while the *bottom panel* shows results for a subject with NT1 narcolepsy. Color codes: white is wake; red is N1 NREM sleep; light blue is N2; dark blue is N3; and black is REM sleep. *(Reproduced with permission from Stephansen JB, Olesen AN, Olsen M, et al. Neural network analysis of sleep stages enables efficient diagnosis of narcolepsy. Nat Commun. 2018;9(1):5229.)*

hypocretin; most patients have normal levels.[77] A study showed that among patients with NT2 who have low hypocretin, all were HLA-DQB1*06:02 positive; only 26% of those with normal hypocretin had gene positivity and those with intermediate levels (110–200 pg/mL) also had higher rates of gene positivity, suggesting a diagnostic cutoff of 200 pg/mL may be more appropriate than 110 pg/mL.[78] Diagnosing NT2 can be challenging, as there is no biomarker present and diagnostic criteria are mostly clinical. Some patients with NT2 progress into NT1 years after the onset of sleepiness. MSLT diagnostic criteria and management for NT2 are similar to those for NT1.

Idiopathic hypersomnia (IH) is less common than narcolepsy; its prevalence is unknown due to lack of diagnostic criteria and robust studies.[79] It is more prevalent in women. Age of onset ranges from 10 to 30 years. There may be a genetic predisposition, as one-third of the patients have positive family history; it is not known to be HLA-associated. The pathophysiology is unclear; some studies show normal levels CSF hypocretin 1 and others show abnormalities in melatonin secretion and the circadian system.[80] One study showed decreased histamine levels in CSF, but a subsequent study was unable to replicate the finding.[81,82]

Hypersomnolence is the key feature that is considered less “irresistible” than in NT1. Patients exhibit “sleep drunkenness” or “severe sleep inertia,” with difficulty awakening in the morning or at the end of naps, which are accompanied by confusion, poor motor coordination, disorientation, and repeated returns to sleep.[79] Naps are few, long, and nonrefreshing; patients have prolonged and undisturbed nocturnal sleep. MSLT shows MSL $\leq$8 min and fewer than two SOREMPS or no SOREMPS if the REM latency in the preceding PSG is $\leq$15 min or a 24-h sleep time is $\geq$660 min during 24-h PSG monitoring (after evaluation of sleep deprivation via actigraphy or a sleep log). High sleep efficiency on the preceding PSG is a supportive finding and, similar to NT2, the diagnosis of IH is a diagnosis of exclusion.

Kleine-Levine Syndrome is a rare and relapsing-remitting hypersomnia associated with cognitive, psychiatric, and behavioral disturbances.[73] It is estimated to affect 1 to 5 cases per million population, with male predominance, especially in the teen years, and a positive family history is common.[83] The etiology is unknown, but the first episode is usually triggered by an infection, suggesting an autoimmune mechanism. Other triggers include alcohol, stress, heat, traumatic brain injury, vaccines, or illicit drugs; the episodes recur usually more than once a year and at least once every 18 months.[69] During episodes, those affected may sleep as long as 16 to 20 h/day, waking up only to eat or void. Additional manifestations include cognitive dysfunction, altered perception, eating disorders (hyperphagia or anorexia), and disinhibited behavior (hypersexuality).[73]

Insufficient sleep syndrome (ISS) must always be considered when evaluating the sleepy patient. ISS affects a large part of the population due to current lifestyle, although the exact prevalence is unknown. Patients complain of EDS, unclear “blackouts,” cognitive symptoms, and involuntary naps with short sleep alternating with long sleep, especially during the weekends. ISS is one of the most important diagnoses in the differential diagnosis of EDS and must be ruled out by actigraphy or sleep log. PSG and MSLT may show features like other hypersomnolent disorders. There may be decreased sleep latency, increased SOREMPs (although this is unlikely from N1 and wakefulness, as in narcolepsy), high sleep efficiency, and increased slow wave sleep (due to rebound effect).[69,74,75] During PSG, when ISS is suspected, instead of ad libitum sleep on the first lab test night, an enforced and extended bedtime (i.e., 9 or 10 h) should be recommended. If no sleep disorder is demonstrated, high sleep efficiency (>90%) and excessive sleepiness on the MSLT the following day are highly suggestive of chronic sleep deprivation.[84] Also, sleep extension and documented adherence to the extended bedtime at home with improvement in symptoms confirms the diagnosis and is an effective management strategy.[84]

Residual EDS in OSA (despite adherence to therapy and normalization of AHI) is an important clinical problem. The prevalence of EDS among positive airway pressure (PAP) adherents (usage of PAP >4 h, for at least 70% of the nights) has been reported to range from 12% to 65%.[85–87] However, prior to making the diagnosis one needs to exclude poor adherence to CPAP, poor mask fit, mask leak, suboptimal pressure, nasal congestion, aerophagia, dry mouth, and treatment-emergent central sleep apnea as well as insufficient sleep. Furthermore, some of the previously mentioned conditions may be responsible for the sleepiness.[88] Even though the mechanism of persistent EDS is unclear, a variety of mechanisms may be responsible. Chronic sleep deprivation and hypoxia-reoxygenation may cause oxidative, irreversible injury in wake-promoting regions of the brain, in particular, the dopaminergic and adrenergic neurons.[88–90] Alterations in the 24-h synthesis and secretion of melatonin, along with alterations in microbiota and acquired dysbiosis, are the other purported mechanisms.[88]

CONCLUSION

Sleep is important in health and wellness. The concept of sleep health is an emerging area of interest.[91] Excessive sleepiness is a very common symptom. In patients with respiratory disease, a sleep disorder may be the presenting disease or may coexist with other disorders. Given the increasing prevalence of sleep disorders and their impact on health, it is imperative that practicing pulmonologists have a sound understanding of sleep medicine and that they can develop a differential diagnosis and orchestrate a management plan for patients with excessive sleepiness.

CHAPTER 102

Perioperative Respiratory Considerations in the Surgical Patient

Horace M. DeLisser
Michael A. Grippi

INTRODUCTION

Postoperative pulmonary complications constitute a significant cause of morbidity and mortality following surgery. Managing patients at risk for postoperative pulmonary problems requires an understanding of the predictable changes in pulmonary physiology that occur with surgery and anesthesia, as well as knowledge of factors associated with development of postsurgical respiratory compromise. Despite the availability of several screening tests, a careful history and physical examination continue to be the cornerstone of preoperative pulmonary evaluation. Although a number of measures can be employed before and after surgery to minimize the risk of respiratory complications, close patient monitoring and early detection are essential.

This chapter focuses initially on changes in pulmonary function with surgery. Pulmonary risk factors before, during, and after surgery are reviewed prior to discussion of preoperative evaluation of the patient for surgery, including lung resectional surgery. Finally, recommendations are made regarding preoperative preparation and postoperative prophylactic measures. Additional discussion of the perioperative care of the patient undergoing resectional lung surgery and development of acute respiratory failure in the surgical patient are addressed in Chapter 104.

CHANGES IN PULMONARY FUNCTION WITH SURGERY

Many postoperative respiratory complications relate to exaggerations of the expected postoperative changes in pulmonary function that occur as a result of the surgery itself, anesthesia, or various pharmacologic interventions.[1,2] Hence, an appreciation of normal postoperative pulmonary physiology is useful in understanding a number of pulmonary problems seen following surgery. Five principal categories of change in pulmonary function with surgery may be considered: (1) lung volumes, (2) diaphragm function, (3) gas exchange, (4) control of breathing, and (5) lung defense mechanisms (Table 102-1).

TABLE 102-1 Changes in Pulmonary Function with Surgery

Reduction in lung volumes
Diaphragm dysfunction
Impaired gas exchange
Respiratory depression due to residual effects of anesthesia or postoperative narcotics
Impaired cough and mucociliary clearance

Lung Volumes

The pattern of pulmonary function abnormalities following thoracic and abdominal surgery is restrictive, characterized by moderate to severe reductions in vital capacity (VC) and smaller, but more important, reductions in functional residual capacity (FRC). The degree of impairment is similar after upper abdominal and thoracic surgery[3–5] and is less for laparoscopic procedures compared with open abdominal procedures.[6] Smaller changes in VC and FRC are noted with lower abdominal surgery; superficial or extremity surgery is usually not associated with any significant or persistent changes in lung volumes.[7,8] During the first 24 h following upper abdominal surgery, VC and FRC may be reduced by more than 70% and 50%, respectively, and they may remain depressed for more than a week.[7–9] Consequently, it is not surprising that pulmonary complications are seen more often with thoracic and upper abdominal procedures than with surgery involving the lower abdomen or extremities (see “Intraoperative Risk Factors,” below).

Reductions in other lung volumes, including total lung capacity (TLC), inspiratory capacity (IC), expiratory reserve volume (ERV), and residual volume (RV) have been noted. While the forced expiratory volume in 1 s (FEV_1) is decreased, the ratio of FEV_1 to the forced vital capacity (FEV_1/FVC%) remains unchanged, indicating that major airway obstruction does not occur.[4]

Since patients undergoing superficial or extremity surgery do not experience major changes in lung volumes, residual or carryover effects from general anesthesia do not appear to play a primary role in this regard. In fact, studies have shown that in many patients, FRC in the early postoperative period is unchanged from baseline. An alternative proposal for the reduction in FRC is that postsurgical pain and associated muscle splinting impair lung mechanics. However, while processes other than pain may be operative, based on the finding that effective pain control using epidural analgesia or intercostal nerve block fails to fully restore VC or FRC to preoperative levels,[10–12] this notion has been challenged.[13] The established consensus is that diaphragm dysfunction is an important contributing factor (see below).[2]

The postoperative reduction in FRC is of major physiologic significance. Its importance can be understood when the phenomenon of airway closure and the concept of closing capacity (CC) are considered.[4]

FRC is the lung volume at the end of a normal tidal expiration. CC is the lung volume at which small airways in the lung bases begin to close during expiration because of a reduction in airway radial traction. The relationship between the two is a key factor in the development of postoperative changes in lung function (Fig. 102-1). In a normal lung, FRC is always greater than CC, and the airways remain open throughout a tidal breath. However, when CC is greater than FRC, lung volume fails to increase sufficiently during tidal breathing to open all the airways and, consequently, some alveolar units remain closed during a breath. Such regions constitute areas of atelectasis. An intermediate state exists when CC exceeds lung volume for part of the time during each tidal breath. Under these circumstances, the airways open for only a portion of the respiratory cycle, creating areas of low ventilation relative to perfusion. In summary, any circumstance that reduces FRC below CC or that increases CC above FRC produces regions of reduced ventilation and atelectasis (Table 102-2).

Diaphragm Function

Diaphragm dysfunction has been recognized as an important factor contributing to the postoperative reduction in lung volumes.[6,11–16] In patients undergoing cholecystectomy, the

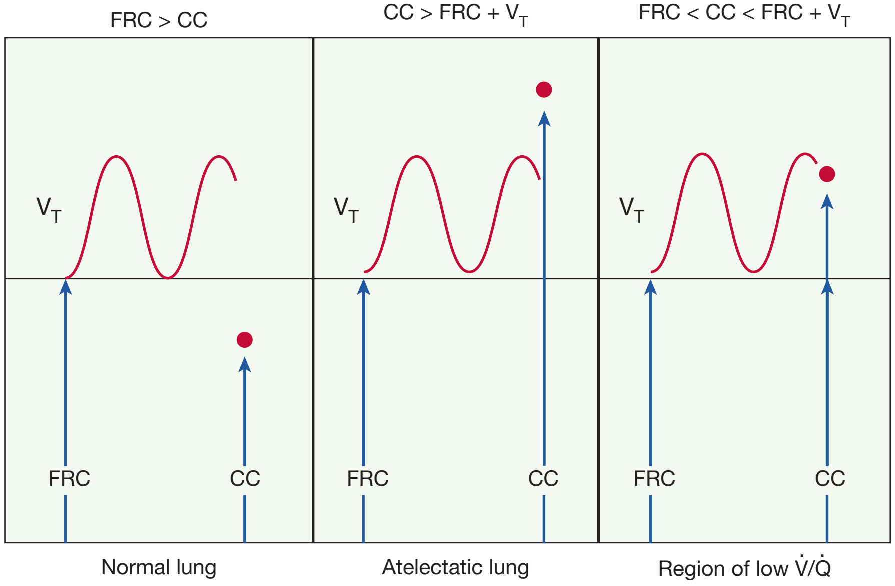

Figure 102-1 The relationship between functional residual capacity (FRC) and closing capacity (CC). V_T, tidal volume. See text. *(Reproduced with permission from Goldmann DR, Brown FH, Guarnieri DM: Perioperative Medicine. New York, NY: McGraw Hill; 1994.)*

diaphragm's contribution to quiet tidal breathing after surgery is reduced.[14] Measurements of transdiaphragmatic pressure during maximal phrenic nerve stimulation following upper abdominal surgery indicate that decreased central nervous system output to the phrenic nerves, possibly as a result of inhibitory reflexes arising from sympathetic, vagal, or splanchnic receptors, may be the important etiologic factor.[15] Studies of the role of pain in this impairment have yielded conflicting results, pointing to either a limited[10–12] or significant[13] role for pain, depending on the procedures used for analgesia.

Gas Exchange

Postoperative arterial hypoxemia occurs commonly, and two phases in its development may be described.[17,18]

The initial phase occurs in the first several hours following anesthesia and surgery. The underlying mechanisms are related largely to the residual effects of the anesthesia and include ventilation–perfusion mismatch, anesthetic-induced inhibition of hypoxic pulmonary vasoconstriction, right-to-left shunting, alveolar hypoventilation, depressed cardiac output, and increased oxygen consumption by peripheral muscles. This phase resolves within 24 h following superficial surgery.

A second phase of hypoxemia, which may persist for several days or weeks, is seen after thoracic and upper abdominal surgery. This phase correlates with reductions in FRC and changes in the FRC–CC relationship. Although alterations in the FRC–CC relationship predominate, other processes may contribute to late postoperative hypoxemia: (1) alveolar hypoventilation (see "Control of Breathing," below); (2) increased dead space ventilation due to rapid, shallow breathing; and (3) decreased mixed venous oxygen tension due to increased oxygen consumption, impaired cardiac output, and reduced oxygen carrying capacity.

TABLE 102-2 Conditions That Alter the Relationship Between Functional Residual Capacity (FRC) and Closing Capacity (CC)

Decrease FRC	Increase CC
Supine position	Advanced age
Obesity	Smoking
Pregnancy	COPD
General anesthesia	Pulmonary edema
Abdominal pain

Control of Breathing

Respiratory depression is a common feature of the postoperative period. Two factors are responsible. First, residual effects of preanesthetic or anesthetic agents inhibit respiratory drive and reduce the ventilatory response to hypercapnia, hypoxia, and acidosis.[19] Second, narcotics given for postoperative analgesia depress both hypercapnic and hypoxic ventilatory drives, resulting in decreased tidal volume, reduced minute ventilation, and increased Pa_{CO_2}.[20] Narcotics also alter the pattern of breathing, reducing the frequency of sighs or eliminating them entirely; in susceptible patients, narcotics may precipitate sleep apnea.

Lung Defense Mechanisms

Several mechanisms protect the lung from environmental and infectious insults. Two of the most important—cough and mucociliary transport—are compromised after surgery, contributing to an increased risk of pulmonary infection.[4,21] Postoperative pain or excessive use of narcotics may inhibit coughing; in addition, altered lung mechanics decrease the expulsive force generated with each cough. Mucociliary clearance is impaired for up to a week following upper abdominal surgery. Although an ineffective cough reflex contributes significantly to reduced mucociliary clearance, several additional mechanisms are involved. These include (1) cilia damage from endotracheal intubation and inhalation of dry, hyperoxic gas mixtures; (2) reduced tracheal mucus velocity due to the presence of an endotracheal tube; (3) anesthetic-induced inhibition of mucociliary transport; and (4) atelectasis.

PULMONARY COMPLICATIONS

The criteria used for defining postoperative pulmonary morbidity have varied considerably in published reports,[22–26] although it is clear that, from a broad perspective, six major categories of complications may be considered: (1) lung parenchymal processes (e.g., atelectasis, pulmonary edema, aspiration pneumonitis, acute respiratory distress syndrome); (2) infection, including acute tracheobronchitis and pneumonia; (3) pleural space processes such pleural effusions and pneumothorax; (4) exacerbation of underlying chronic lung disease; (5) respiratory insufficiency/failure requiring supplemental oxygen or ventilatory support; and (6) thromboembolic disease. With thoracic surgery, several additional problems may occur;[27–40] these are summarized in Table 102-3.

TABLE 102-3 Pulmonary Complications Associated with Thoracic Surgery

Procedure	Complication	Incidence (%)	References
Coronary artery bypass grafting	Phrenic nerve damage[a]	10–20	27–29
	Pleural effusions (postpericardiotomy syndrome)	10–15	30
Lung resection surgery	Pleural space complications (bronchopleural fistula, prolonged air leaks, or empyema[b])	5–20	31–36
Median sternotomy	Sternal wound infection (mediastinitis or osteomyelitis)	1–4	37,38
Esophagectomy	Anastomotic leak	3–12	39,40

[a] *Incidence for clinically significant injury with prolonged mechanical ventilation is 1% to 2%.*
[b] *Rates higher for patients undergoing resection for aspergilloma.*

TABLE 102-4 Factors Associated with Development of Postoperative Pulmonary Complications

Preoperative	Intraoperative	Postoperative
Chronic lung disease	Type of anesthesia	Immobilization
Smoking	Duration of anesthesia	Inadequate pain control
General state of health	Surgical site	
Age	Type of surgical incision	
Obesity	Nonprotective mechanical ventilation	
Nutritional status	Emergent nature of the procedure	
Antecedent respiratory tract infection		

TABLE 102-5 Relative Strength of Preoperative Risk Factors Associated with the Development of Postoperative Pulmonary Complications

Factor	Odds Ratio
General state of health (ASA class >II)	2.55–4.87
Congestive heart failure	2.93
Albumin <3.5 g/L	2.53
Age >60 years	2.09–3.04
COPD	1.79
Functional dependence	1.65–2.51
Weight loss	1.62
Impaired sensorium	1.39
Cigarette smoking	1.26
Alcohol use	1.21
Antecedent respiratory tract infection	Risk not known
Obesity	No increased risk for major morbidity

The variability in defining postoperative pulmonary complications has resulted in reported incidences that have ranged widely in the literature, depending on the patient population sampled and the procedures studied. In general, a healthy, young nonsmoker of normal weight has a very low risk of postoperative pulmonary complications (1% or less).[41] However, a number of factors are associated with the development of postoperative pulmonary complications (Table 102-4).[22–26,42–47] They include preoperative factors (chronic lung disease, smoking, general state of health, age, obesity, nutritional status, and antecedent respiratory tract infection), intraoperative factors (the emergent nature of the procedure, type and duration of anesthesia, location of surgical site, type of surgical incision and nonprotective lung ventilation), and postoperative factors (inadequate pain control and immobilization). Tables 102-5 and 102-6 list, respectively, the relative strengths of preoperative and intraoperative factors associated with development of postoperative pulmonary complications based on odds ratios.[23,48]

PREOPERATIVE RISK FACTORS

A number of patient-related factors have been implicated in the development of postoperative respiratory complications.[23] They include the presence of chronic lung disease (particularly

TABLE 102-6 Relative Strength of Intraoperative Risk Factors Associated with the Development of Postoperative Pulmonary Complications

Factor	Odds Ratio
Surgical Site	
Aortic aneurysm repair	6.90
Thoracic surgery	4.24
Abdominal surgery	3.01
Neurosurgery	2.53
Head and neck surgery	2.21
Vascular surgery	2.10
Gynecologic or urologic surgery	Not a risk factor
Hip surgery	Not a risk factor
Procedure-Related Issues	
Duration of surgery >2.5–4.0 h	2.26
Emergency surgery	2.21
General anesthesia	1.83

obstructive airway disease); the patient's overall state of health, age, and history of cigarette smoking; and the presence of comorbid conditions, including malnutrition, congestive heart failure, alcohol use, functional dependence, and impaired sensorium. The risk for major postoperative pulmonary complications associated with obesity appears to be modest, while the precise risk associated with recent respiratory viral infections is unknown.

■ Chronic Lung Disease

The following discussion focuses on the operative risks in patients who have one of four common categories of chronic lung disease: (1) chronic obstructive pulmonary disease (COPD), (2) restrictive lung diseases, (3) obstructive sleep apnea (OSA), and (4) pulmonary vascular diseases.

Chronic Obstructive Pulmonary Disease

Most studies addressing the impact of pre-existing lung disease on surgical risk have focused on COPD, which has been identified as a significant risk for development of postoperative pulmonary complications.[42,43,46,49–59] The reported incidence of postoperative pulmonary complications in patients with COPD varies from 10% to greater than 50% and is influenced by type of surgery, magnitude of pre-existing respiratory impairment, and criteria used to define complications. Although not precisely quantified in the literature, the risk for postoperative respiratory complications appears to increase significantly when the FEV_1 is below 65% of predicted. Evidence shows that the risk for postoperative respiratory complications in COPD may be raised further by the concomitant presence of resting hypoxemia.[60] Although an increased risk has been suggested for patients who are hypercapnic at rest,[49,61] whether hypercapnia is, in fact, an independent predictor of pulmonary complications after surgery is unclear.[62]

In patients with severe disease, an important issue is whether a critical level of lung function exists below which the risk of developing a major, potentially life-threatening pulmonary complication is so high as to make anesthesia and surgery too dangerous. In the past, such a prohibitive threshold or level was proposed. Subsequent studies, however, have failed to support this hypothesis.[63] Patients with an FEV_1 as low as 450 mL have been found to tolerate surgery safely.[61] Hence, patients should not be denied necessary operative procedures solely on the basis of marginal lung function. As with all medical interventions, the potential benefits of the operative procedure must be weighed against the operative risk.

The increased incidence of postoperative pulmonary complications in patients with COPD is due, in part, to an increase in the CC, favoring development of areas of low ventilation-to-perfusion ratios and atelectasis. In addition, in patients who continue to smoke, impaired ciliary function and chronic tracheobronchitis may be contributing factors.

Restrictive Lung Diseases

The risk of pulmonary complications in patients with restrictive lung diseases who undergo surgery is unknown. Although some experience has been reported with patients having thoracic or corrective orthopedic surgery (see below), very little data exist with regard to abdominal and extremity surgery. One might expect a higher incidence of postoperative respiratory complications in these patients for two reasons: (1) FRC is reduced, favoring the formation of areas of poor ventilation and atelectasis; (2) coughing and the ability to clear respiratory secretions are impaired.

Experience with postoperative pulmonary complications has been reported in three relatively common situations for patients with restrictive disorders: (1) sarcoidosis complicated by aspergilloma and hemoptysis, (2) corrective surgery for kyphoscoliosis, and (3) myasthenia gravis with associated thymoma.

Sarcoidosis may progress to diffuse interstitial fibrosis and cavitary changes, primarily involving the upper lobes (Chapter 53). The cavities are prone to infection with *Aspergillus* species and aspergilloma formation, with subsequent development of recurrent and, at times, life-threatening, hemoptysis. Affected patients generally have very poor lung function and, hence, are managed conservatively. However, if supportive medical therapy fails, patients may require thoracotomy and lung resection. These procedures can be done with low mortality, but they may be complicated by empyema, chylothorax, prolonged pulmonary parenchymal air leaks, or bronchopleural fistulae.[33–36]

Corrective surgery in patients with kyphoscoliosis may involve anterior or posterior spinal fusion procedures or a combination of the two.[64,65] In addition to correction of the primary orthopedic abnormality, an important indication for performing these procedures is progressive deterioration of pulmonary function. Postoperative respiratory complications have been reported in up to 20% of patients, including pleural space–related processes (e.g., pneumothorax, pleural effusion, bronchopleural fistula, and empyema) and lobar or total lung atelectasis.[65–67] Important risk factors include (1) nonidiopathic scoliosis, (2) open anterior spinal fusion procedures, (3) age greater than 20 years, (4) intellectual disability (general learning disability), (5) preoperative hypoxemia, and (6) obstructive pulmonary function tests.[66] Thoracotomy has been associated with a significant decrease in pulmonary function for up to 2 years after surgery.[65,68] Video-assisted thoracoscopic surgery (VATS) has emerged as an alternative to open thoracotomy; the outcomes of anterior fusion via VATS and thoracotomy are similar.[69,70]

The majority of patients with myasthenia gravis will, during the course of their disease, undergo thymectomy, which appears to improve long-term outcomes.[71] Surgical options for thymectomy include the long-established method of transsternal resection, a transcervical approach, a combined transsternal–transcervical procedure, and, more recently, VATS.[72,73] Video-assisted thoracoscopic thymectomy is an increasingly common approach, with outcomes equivalent or superior to more invasive procedures.[73]

Historically, up to 30% of patients undergoing thymectomy required mechanical ventilation for more than 3 days following the transsternal approach.[74,75] Reported risk factors for postoperative pulmonary complications following transsternal resection include chronic myasthenia gravis (>6 years), severe bulbar weakness, pre-existing respiratory illness, need for large doses of pyridostigmine, and reduced maximal static expiratory pressure (<50 cm H_2O or 66% of predicted).[74–76] Preoperative VC has not proved a consistent predictor of respiratory morbidity following thymectomy. More recent routine use of plasma exchange in patients with bulbar or generalized myasthenia gravis has significantly reduced the duration of postoperative ventilatory support and time in the intensive care unit following transsternal thymectomy.[72]

Virtually all patients with myasthenia gravis are treated with anticholinesterases, which are usually discontinued prior to surgery to minimize tracheobronchial secretions. Controversy exists, however, regarding whether these agents should be restarted immediately after surgery or withheld for 24 to 48 h following thymectomy.

Obstructive Sleep Apnea

OSA is common, with a prevalence of 5% or higher, depending on the population studied (Chapter 98). For many of these patients, the diagnosis of OSA is not established preoperatively.[77] Unrecognized OSA is significant because both anesthesia and surgery affect sleep architecture;[78] in addition, use of postoperative narcotics for analgesia may further blunt ventilatory chemosensitivity,[79] suggesting that postoperative respiratory morbidity is likely higher in patients with OSA than in the general population. Although initial studies were consistent with this expectation,[80] subsequent reports have failed to show that OSA is significant risk factor for development of major postoperative pulmonary complications.[81–84] Thus, while it is prudent, and in the patient's best interest to use the preoperative evaluation as an opportunity to screen for OSA, the value of preoperative screening for OSA as a means of decreasing postoperative pulmonary complications has not been established.

Pulmonary Vascular Diseases

The risk of postoperative pulmonary complications in patients with underlying pulmonary vascular disease and intact respiratory mechanics is not known. However, one might anticipate an exaggeration of, or prolongation in, the hypoxemia seen postoperatively (see "Gas Exchange," above). In addition, pulmonary reserve in these patients is usually reduced; hence, additional pulmonary insults are less likely to be tolerated.

■ Smoking History

That smoking increases the risk of postoperative respiratory complications, even among those without COPD, has long been recognized.[50,85] Given the well-documented adverse effects of smoking on respiratory epithelium and pulmonary function, the magnitudes of which correlate with the degree of tobacco consumption, such an association is not surprising.

In individuals undergoing coronary artery bypass graft surgery, the risk of smoking becomes significant when tobacco use exceeds 20 pack-years.[86] A statistically significant reduction in complications occurs only when patients discontinue smoking for at least 8 weeks prior to surgery. This finding is consistent with studies showing that abnormalities in pulmonary function may persist up to several months after smoking cessation.[87,88] Although smoking cessation of more than 2 months is associated with a decreased risk of postoperative respiratory complications, early retrospective studies actually showed a paradoxical *increase* in pulmonary complications in patients who stopped smoking only a few weeks or days prior to surgery.[89] However, more recent studies[90] and analyses[91] have failed to demonstrate increased pulmonary complications in patients who quit smoking within 2 months of surgery.

■ General State of Health

Overall clinical status, as categorized by the American Society of Anesthesiologists' (ASA) classification (Table 102-7), correlates with development of postoperative pulmonary complications.[56,92–94] Specifically, an ASA classification of II or higher is a powerful predictor of increased risk for respiratory problems after surgery.[23,46,47]

■ Age

Although increased age was previously thought to be a minor risk factor for postoperative respiratory complications,[95] more recent analyses indicate that increasing age is, in fact, a significant independent predictor, even after accounting for comorbid conditions associated with aging.[23] Advanced age, however, should not be the sole reason for withholding surgery, particularly lung resection.

In one important study, despite the finding of a higher 30-day postoperative mortality in patients over age 70 years who underwent resectional lung surgery, the incidence of postoperative pulmonary complications and hospital stay were not increased, and survival was not decreased, in the older group.[96] Further, in a nested, case-control study of patients greater than age 70 years who underwent lung resection, no significant differences were found between the elderly and younger controls in length of stay, major morbidity, or operative mortality.[97] These findings, along with other published results,[98] indicate that treatment decisions should be individualized for each patient.

TABLE 102-7 American Society of Anesthesiologists (ASA) Clinical Classification

ASA I	Otherwise healthy patient undergoing elective surgery
ASA II	Patient with single-system or well-controlled disease that does not affect daily life
ASA III	Patient with multisystem or well-controlled major-system disease that limits daily activity
ASA IV	Patient with severe, incapacitating disease that is poorly controlled or end stage
ASA V	Patient who is in imminent danger of death and is not expected to survive 24 h

■ Obesity

A number of changes in respiratory mechanics and pulmonary function occur with obesity.[99–102] The accumulation of fat in the chest wall, diaphragm, and abdomen may reduce total respiratory compliance by more than 60%—a change that is amplified when the patient assumes the supine position.[103] The reduced compliance, in turn, increases the work of breathing.[99,100] Consequently, minute ventilation, oxygen consumption, and carbon dioxide production are further increased beyond baseline values, which are already elevated as a result of increased metabolic demands imposed by the obese state. In terms of gas exchange, modest effects at rest are observed only in morbidly obese individuals: lower than predicted Pa_{O_2}, higher than predicted alveolar-to-arterial oxygen pressure difference, normal blood oxygen saturation, and normal Pa_{CO_2}.[104]

Typically, spirometry in obese patients does not indicate airway obstruction. However, a reduction in ERV is found consistently. The magnitude of the reduction correlates with the degree of obesity. Areas of low ventilation relative to perfusion and atelectasis are seen (see "Lung Volumes," above). In addition to these changes, obese patients appear to have a larger gastric volume and lower gastric pH than do nonobese patients and may be predisposed to aspiration.[105]

Morbidly obese patients may be at an increased risk for development of atelectasis, as noted on chest radiographs.[106,107] However, when bacterial pneumonia, acute respiratory failure, or prolonged mechanical ventilation are considered, and confounding factors are excluded, obese patients undergoing abdominal surgery do not show an increased incidence of clinically significant postoperative pulmonary complications compared with nonobese patients.[41,108–110] Further, respiratory complications occur in only 4% to 7% of obese patients undergoing gastric bypass surgery and appear to be declining.[111,112] Therefore, in the absence of concurrent cardiopulmonary disease, the risk of postoperative pulmonary complications associated with obesity appears not to be excessive. However, as noted previously, obesity is clearly a risk factor for OSA syndrome, which may be unmasked or exacerbated because of use of postoperative analgesics or narcotics.[113]

■ Nutritional Status

The effects of malnutrition and severe starvation on the respiratory system include a reduced ventilatory response to hypoxia, decreased diaphragmatic muscle function, impaired cell-mediated and humoral immunity, and alterations in the elastic properties of the lung. Depending on the clinical metrics examined (e.g., weight loss >10% over the previous 6 months, BMI <20 kg/m^2), the screening procedures utilized (e.g., Mini Nutritional Assessment [MNA] score <17), and the laboratory tests employed (e.g., serum albumin <36 g/L), malnutrition may be found in 50% or more of hospitalized patients.[114,115] Evidence exists that these levels of malnutrition are associated with expiratory muscle weakness (despite preservation of pulmonary function)[116] and an increased incidence of postoperative respiratory complications.[42,108,117,118] However, aggressive preoperative nutritional support has not been shown to decrease postsurgical pulmonary morbidity.[119]

Antecedent Respiratory Tract Infection

The effects of an antecedent respiratory tract infection on the incidence of respiratory complications following surgery are difficult to predict. With respiratory syncytial virus (RSV) infections, symptoms typically resolve in 7 to 10 days; viral shedding averages 10 to 13 days, but it may persist beyond 20 days.[120,121] Furthermore, enhanced airway reactivity and increased airway resistance associated with this and other viral infections may persist for weeks beyond resolution of acute symptoms.[122,123] In addition, diaphragmatic function may be impaired during viral infections.[124]

In pediatric patients, perioperative, non-life-threatening, adverse respiratory events are more common in patients with recent (within 4 weeks) upper respiratory tract infections compared with those without infections.[125,126] In an adult population, history of an acute respiratory infection in the month preceding surgery is an independent risk factor for development of a postoperative pulmonary complication.[45] Therefore, in the setting of an active or recent respiratory tract infection (in the previous 2 weeks), a 2- to 4-week delay in elective surgery is generally advised.

Other Patient-Related Factors

Other factors have been reported to be associated with an increased incidence of postoperative pulmonary complications.[23] These include congestive heart failure,[45,127,128] preoperative functional dependence, impaired sensorium (acute confusion or delirium), and active alcohol use (>2 drinks per day in the past 2 weeks).[42,43]

INTRAOPERATIVE RISK FACTORS

Several operative factors have been associated with development of pulmonary complications after surgery. These include whether the surgery is emergent or nonemergent, type of anesthesia used, length of the procedure (as determined by the duration of anesthesia), surgical site, and type of surgical incision and nonprotective mechanical ventilation.

Emergent Nature of the Procedure

Postoperative pulmonary complication rates are higher for surgeries done on an emergent basis.[42,43,45–47,53,54,127] The increased risk of emergency surgery may be significant[23] and may be related to loss of the ability to implement some of the preventative measures outlined subsequently or to deliberately plan the anesthetic strategy.

Type of Anesthesia

The pulmonary effects of general anesthesia have been implicated in the development of postoperative pulmonary complications.[42,43,56,57] They include impairment of oxygenation and carbon dioxide elimination. These effects result from anesthetic-induced changes in the shape and motion of the chest wall and diaphragm, which, in turn, lead to increases in alveolar dead space, shunt fraction, and ventilation–perfusion mismatching. Alterations in lung function may contribute to pulmonary morbidity.

Because of the effects of general anesthesia on gas exchange, regional anesthesia (spinal or epidural anesthesia) or local anesthesia with monitored anesthesia care (MAC) have been used as alternatives, particularly in patients with underlying pulmonary disease. Indeed, epidural anesthesia to a T4 sensory level does not appear to alter FRC, VC, FEV_1, the alveolar–arterial oxygen gradient, shunt fraction, or cardiac output.[129] Overall, regional anesthesia, as compared with general anesthesia, decreases the risk of postoperative respiratory complications, particularly deep-vein thrombosis.[130,131] These beneficial effects, however, appear to be most significant for abdominal and thoracic procedures[132,133] and less so for nonthoracoabdominal procedures, such as carotid endarterectomy[134,135] and hip fracture surgery.[136,137]

Duration of Anesthesia

The incidence of pulmonary complications increases significantly for procedures lasting longer than 2 to 4 h.[45,50,51,75,93] Patients whose procedures last 4 h or more are five times more likely to experience postoperative pneumonia than those whose procedures last less than 2 h.[108]

Surgical Site

Development of postoperative pulmonary complications has long been recognized to correlate strongly with the anatomic site of operation.[45,50,51,75,93] The complication rate (excluding thromboembolic disease) is less than 5% for gynecologic and urologic procedures, 5% to 10% for lower abdominal and head and neck surgeries, and 10% to 20% for upper abdominal surgeries. Abdominal aortic surgery is associated with a pulmonary complication rate of 25% or more.[23]

Reported postoperative complication rates for thoracic surgery involving lung resection vary from under 10% to 40% or higher.[138–143] Postoperative respiratory morbidity following lung resection surgery (in addition to all the factors cited earlier) also depends on a number of other issues, including (1) the presence of underlying lung disease, (2) the amount of functional lung removed, and (3) the extent to which the "bellows" function of the lung is impaired (see "Evaluation for Lung Resection," below). Furthermore, the potentially higher incidence of postoperative respiratory complications after lung resection surgery relative to other procedures also reflects the occurrence of specific problems related to entering the pleural space or resection of lung tissue (e.g., development of pleural effusion, empyema, pneumothorax, or persistent pulmonary parenchymal air leak).

Type of Surgical Incision

For abdominal procedures, vertical laparotomy incisions may carry a higher incidence of postoperative complications than do horizontal incisions,[144] although this finding has been questioned.[145] Abdominal laparoscopic procedures and thoracoscopic lung resection have gained widespread acceptance because of reduced patient discomfort, shortened length of hospitalization, and faster patient return to full activity. Since the magnitude of incisional pain is usually less, and since patients typically ambulate sooner, the incidence of postoperative respiratory complications with these less invasive procedures is likely to be lower. Laparoscopic cholecystectomy, when compared with open cholecystectomy, demonstrates better preservation and faster recovery of lung volumes, higher arterial oxygen saturations, less postoperative pain and analgesia use, and a lower incidence of postoperative pulmonary complications.[146–148] Comparable findings have been noted for minimally invasive esophagectomies compared with open procedures, and for video-assisted thoracic surgery versus open thoracotomy.[32]

Nonprotective Mechanical Ventilation

To prevent hypoxemia and atelectasis in anesthetized patients, intraoperative ventilatory support has typically involved the use of large tidal volumes (10–15 mL/kg of predicted body weight). This approach, however, may induce alveolar overdistension and lung injury and increase the risk of postoperative pulmonary complications.[149,150] In contrast, postoperative respiratory complications are decreased when an intraoperative lung protective ventilation strategy is employed, including low tidal volumes (6–8 mL/kg of predicted body weight), modest levels of positive end-expiratory pressure (PEEP) (6–8 cm H_2O), and recruitment maneuvers (periodic hyperinflation of the lungs every 30 min after intubation).[151]

POSTOPERATIVE RISK FACTORS

Inadequate pain control, prolonged bed rest, and patient inactivity contribute to development of postoperative respiratory complications.

Inadequate Postoperative Analgesia

Effective pain control is vital in the early postoperative period, since pain inhibits coughing and deep breathing and discourages early mobilization—factors that contribute to an increased risk of pulmonary complications. More importantly, there is evidence that effective analgesia after thoracic or abdominal surgery reduces the occurrences of postoperative pulmonary complications.[152–155] Obstacles to good postoperative analgesia include hesitancy of the patient to report pain for fear of being labeled a "bad" patient and anxiety of caregivers in administering narcotics because of side effects.

Immobilization

Prolonged bed rest and inactivity following surgery impact the risk of postoperative respiratory complications in several ways. FRC decreases by 500 to 1000 mL in moving from the upright to the supine position, favoring development of atelectasis.[18] Increased ambulation is associated with better clearance of respiratory secretions. Postoperative immobilization is a major risk factor for development of deep venous thrombosis and pulmonary embolism.

PREOPERATIVE EVALUATION

The principal elements in preoperative evaluation of the surgical patient are (1) the history and physical examination, (2) the chest radiograph, (3) arterial blood gas analysis, and (4) pulmonary function tests (Fig. 102-2).

History and Physical Examination

A careful history is an essential component of preoperative evaluation. The following issues should be reviewed: (1) smoking history; (2) history of respiratory symptoms (e.g., cough, chest pain, dyspnea), including symptoms of sleep apnea; (3) extent of pre-existing lung disease; and (4) history of recent respiratory tract infection. The physical examination is rarely helpful in identifying pulmonary risk factors. When the history is negative, the physical examination is typically unremarkable. However, the initial physical examination supplements the history and provides a baseline for future comparisons.

Chest Radiograph

The preoperative chest radiograph is usually unrevealing if risk factors and abnormal physical findings are absent.[156,157] Although the admission or screening chest radiograph is more likely to show an abnormality in individuals with known cardiopulmonary disease, the study usually simply confirms the presence of previously known abnormalities; only occasionally does it result in an alteration in management. Thus, a preoperative chest radiograph is indicated when there are new or unexplained symptoms or signs, when there is a history of underlying lung disease and no recent chest radiograph, or when thoracic surgery is planned.

Arterial Blood Gas Analysis

Since an elevated Pa_{CO_2} is associated with an increased incidence of postoperative respiratory morbidity in patients with significant chronic lung disease, an arterial blood gas analysis should be done preoperatively in these patients.[60] Although supportive data are lacking, it is common practice to obtain an arterial blood gas sample in all patients undergoing lung resection surgery, even those without significant underlying lung disease. The determination serves as a basis for comparison with subsequent intra- and postoperative measurements. It is also recommended that an arterial blood gas specimen be obtained in patients who, by either history or physical examination, have a new significant pulmonary process. Data do not support the use of arterial blood gas analysis as a routine preoperative screening test.[158]

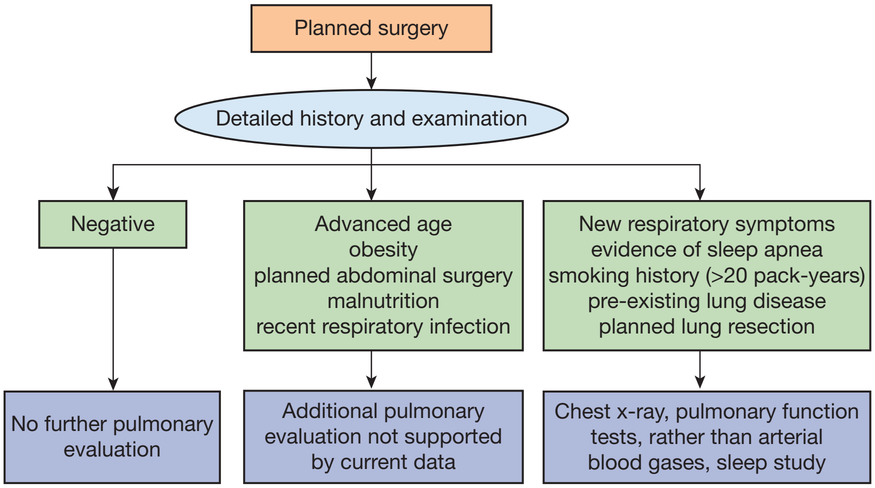
Pulmonary Function Tests

An increased risk of postoperative respiratory complications has been demonstrated only with obstructive pulmonary disorders. Although theoretical reasons may prompt expectation of a higher incidence of postoperative respiratory problems in patients with restrictive lung diseases (see "Preoperative Risk Factors," above), currently, data demonstrating a correlation between the degree of restriction (as assessed by lung volumes) and postoperative pulmonary morbidity are lacking. Hence, although a complete battery of pulmonary function tests is useful in evaluating suspected restrictive lung disease, spirometry to evaluate for airway obstruction is all that is required to screen patients at risk for postoperative pulmonary complications.

Indications for preoperative pulmonary function testing include the presence of cough or unexplained dyspnea, a history of chronic lung disease, a history of cigarette smoking (>20 pack-years), or planned lung resection (see below). Current data do not support the routine use of these studies to evaluate the pulmonary risks of advanced age, obesity, malnutrition, or abdominal surgery.[159–162] Finally, normal pulmonary function tests obviously do not guarantee a complication-free postoperative course and do not lessen the need for diligent respiratory care following surgery.

EVALUATION FOR LUNG RESECTION

In evaluating patients for lung resection, the clinician must consider two broad issues: (1) What is the surgical morbidity and mortality for the patient with significant underlying chronic lung disease? (2) Will postoperative lung function be adequate to support a reasonable quality of life? Pulmonary function



Planned surgery
Detailed history and examination
Negative
Advanced age
obesity
planned abdominal surgery
malnutrition
recent respiratory infection
New respiratory symptoms
evidence of sleep apnea
smoking history (>20 pack-years)
pre-existing lung disease
planned lung resection
No further pulmonary evaluation
Additional pulmonary evaluation not supported by current data
Chest x-ray, pulmonary function tests, rather than arterial blood gases, sleep study

Figure 102-2 Algorithm for preoperative pulmonary evaluation. See text for discussion.

testing, supplemented by exercise testing in selected cases, provides the basis for answering these questions.[163,164]

Pulmonary Function Testing

Studies dating back to the 1950s have shown that the risk of postoperative respiratory complications following pneumonectomy increases significantly when the FEV_1 is less than 2 L or 80% of predicted normal, or when the maximal voluntary ventilation (MVV) is less than 50% of predicted.[165] For a lobectomy, an FEV_1 of 1.5 L appears to be the critical threshold. The diffusion capacity for carbon monoxide (DL_{CO}) also has been identified as a predictor of postoperative complications.[166,167] Increased risk is associated with a DL_{CO} of less than 60% to 80% of predicted and appears to be independent from FEV_1 as a predictor of complications, morbidity, and death.[168–170] Therefore, predictive postoperative lung function should be estimated for patients with an FEV_1 or DL_{CO} less than 80% of predicted.[163,164]

Prediction of Postoperative FEV_1 or DL_{CO}

Ventilation–perfusion lung scans measure the relative blood flow or ventilation to one lung or lung region and can be used to predict postoperative FEV_1 or DL_{CO} using the following equation:

$$\begin{aligned}&\text{Predicted postoperative } FEV_1 \text{ or } DL_{CO} = \text{Preoperative } FEV_1\\ &\quad \text{or } DL_{CO} \times \text{(lung function remaining after resection,}\\ &\qquad \text{as determined by radionuclide imaging)} \qquad (1)\end{aligned}$$

An alternative approach to estimating the predicted postoperative pulmonary function involves a calculation based on the number segments of the lung (10 on the right and 9 on the left)[171] as follows:

$$\begin{aligned}&\text{Predicted postoperative } FEV_1 \text{ or } DL_{CO} = \text{Preoperative } FEV_1\\ &\quad \text{or } DL_{CO} \times \text{(lung function remaining after resection,}\\ &\qquad \text{as determined by radionuclide imaging)} \qquad (2)\end{aligned}$$

Studies comparing the radionuclide imaging-based technique versus the segment-based method suggest that perfusion imaging, overall, provides a better prediction of postoperative lung function, as the segment method underestimates lung function after pneumonectomy.[172,173]

In addition to the two methods noted earlier, other approaches have been employed to predict postresection lung function. However, procedures such as quantitative computed tomographic (CT) imaging[174] have failed to gain wide acceptance, and oxygen-enhanced MRI,[175] although promising, awaits further development.

A number of studies have demonstrated that the perioperative risk for lung resection increases significantly when the predicted postoperative FEV_1 or DL_{CO} is less than 40% of predicted.[166,176–179] Therefore, a predicted postoperative FEV_1 or DL_{CO} of at least 40% predicted has been proposed as useful criteria for undertaking "safe" pulmonary resection.[163,180] Finally, with recognition that most patients who undergo resectional lung surgery have lung cancer, and that this malignancy has virtually a 100% mortality without surgery (for non–small-cell tumors), caution must be exercised in applying exclusionary criteria for surgery.

Exercise Testing

A number of investigators have found measurement of maximal oxygen consumption ($\dot{V}_{O_2max}$) during cardiopulmonary exercise testing to be useful in predicting postoperative morbidity and mortality.[181–185] Specifically, a $\dot{V}_{O_2max}$ of less than 15 to 20 mL/kg/min is associated with an increased incidence of postoperative complications. Cardiopulmonary exercise testing is, therefore, used to further assess the operability of patients of who would be at high risk for surgery based on determination of predicted postoperative pulmonary function.[163]

If cardiopulmonary exercise testing is unavailable, two technologically simpler approaches, stair climbing and a walking test, can be used to assess a patient's fitness for lung resection. Although standardization of the stair climbing test may be problematic, demonstration of a patient's ability to climb five flights of stairs predicts a $\dot{V}_{O_2max}$ greater than 20 mL/kg/min; patients who are unable to climb one flight of stairs have a $\dot{V}_{O_2max}$ less than 10 mL/kg/min.[186] Furthermore, an ability to climb three flights of stairs reliably identifies patients who are likely to do well after a lobectomy, despite having a predicted postoperative FEV_1 or DL_{CO} that is <40% of predicted.[187,188]

The shuttle walk and 6-min walk tests also have been investigated as alternatives to cardiopulmonary exercise testing. For the shuttle walk, the patient walks back and forth over a distance of 25 m at a progressively faster rate. Inability to complete 25 shuttles approximates a $\dot{V}_{O_2max}$ less than 10 mL/kg/min.[189,190] A 6-min walk distance greater than 1000 ft has been reported as predictive of successful surgical outcome.[177]

Recommended Approach

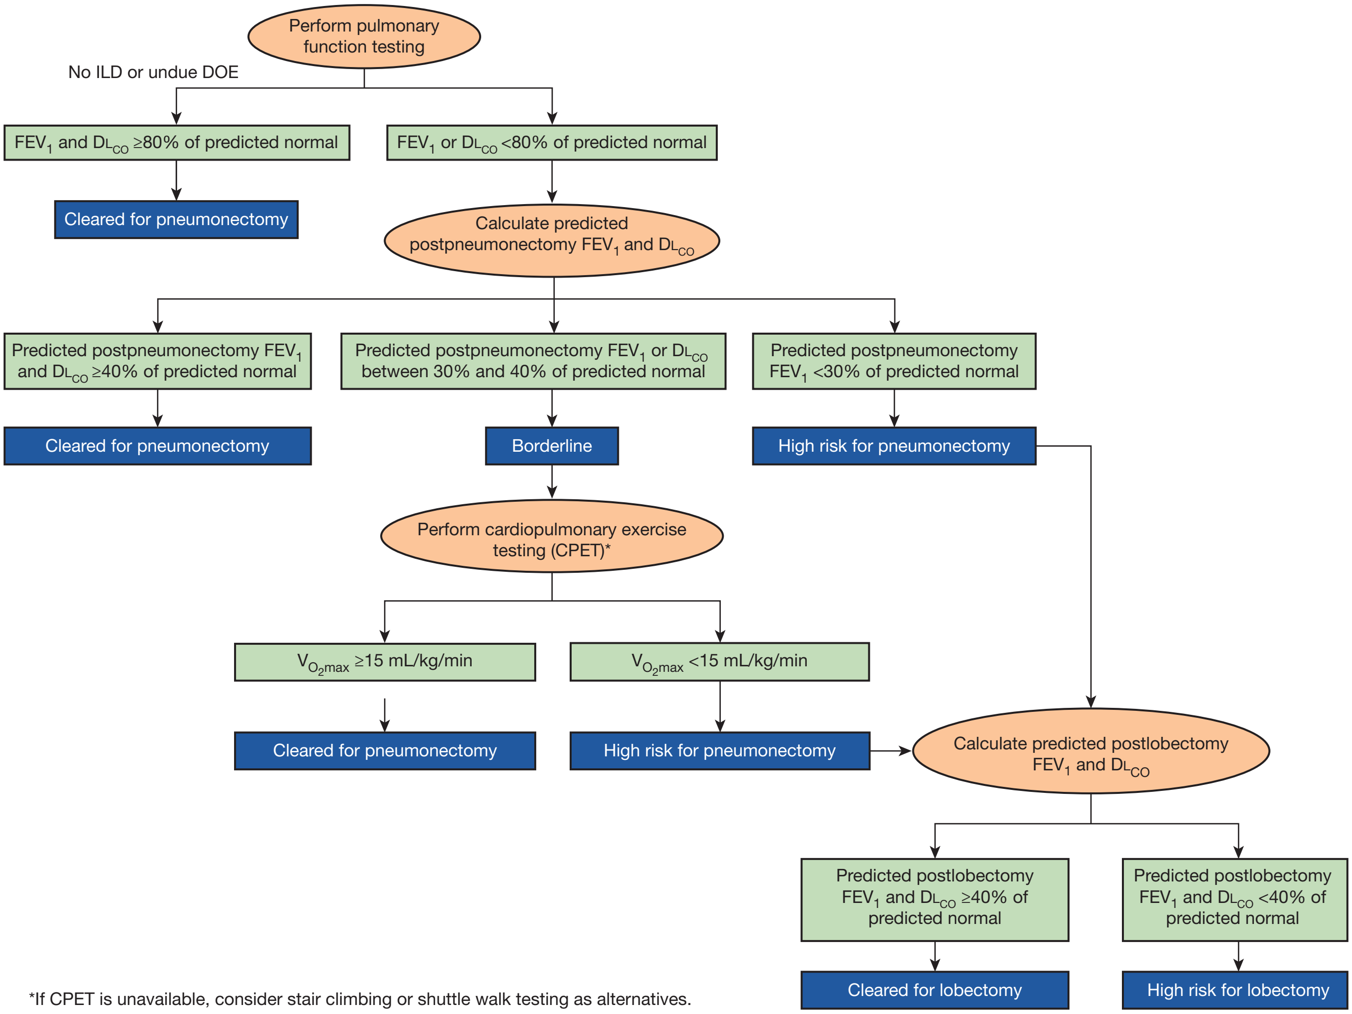
Summarized in Fig. 102-3 is a recommended sequence for evaluating patients for lung resection. The approach is adapted from recommendations of the American College of Chest Physicians (ACCP),[163] which, despite some differences, is also consistent with guidelines from several European professional societies.[164,180] The approach is predicated on determining the patient's operability for pneumonectomy, should this procedure be deemed necessary at the time of surgery (e.g., to permit complete removal of a tumor or to deal with an unanticipated intraoperative complication):

- If the preoperative FEV_1 and the DL_{CO} are greater than or equal to 80% predicted normal and the patient has no dyspnea on exertion or interstitial lung disease, the patient is cleared for pneumonectomy; no further testing is required.
- If the preoperative FEV_1 or the DL_{CO} are less than 80% predicted normal, the predicted postpneumonectomy FEV_1 and DL_{CO} should be estimated.
- If the predicted postpneumonectomy FEV_1 and DL_{CO} are greater than or equal to 40% of predicted normal, the patient is cleared for pneumonectomy and no further testing is required.
- If the predicted postpneumonectomy FEV_1 is less than 30% predicted normal, the patient is considered at high risk for a pneumonectomy.
- If the patient is considered at borderline risk for pneumonectomy (the predicted postoperative FEV_1 or DL_{CO} is less than 40% but at least 30 predicted normal), exercise testing should be done. Borderline patients with a $\dot{V}_{O_2max}$ greater than or equal to 15 mL/kg/min are cleared for pneumonectomy (no further testing is required), while patients with $\dot{V}_{O_2max}$ less than 15 mL/kg/min are considered at high risk for a pneumonectomy.
- If the patient is determined to be at high risk for pneumonectomy, the predicted postlobectomy FEV_1 and DL_{CO} should be determined to inform conversations about the risks and benefits of more limited surgical resections or nonoperative treatment options.

For selected, high-risk patients with emphysema and potentially resectable lung cancer, consideration should be given for a segmental resection[191] or combined cancer resection and lung volume reduction.[192] The latter is particularly worth considering if the emphysema is heterogeneous and primarily involves the lobe to be resected.

PREOPERATIVE PREPARATION

Relatively few studies have specifically addressed the question of whether aggressive, preoperative pulmonary preparation decreases



Perform pulmonary function testing
No ILD or undue DOE
FEV_1 and DL_{CO} ≥80% of predicted normal
FEV_1 or DL_{CO} <80% of predicted normal
Cleared for pneumonectomy
Calculate predicted postpneumonectomy FEV_1 and DL_{CO}
Predicted postpneumonectomy FEV_1 and DL_{CO} ≥40% of predicted normal
Predicted postpneumonectomy FEV_1 or DL_{CO} between 30% and 40% of predicted normal
Predicted postpneumonectomy FEV_1 <30% of predicted normal
Cleared for pneumonectomy
Borderline
High risk for pneumonectomy
Perform cardiopulmonary exercise testing (CPET)*
$V_{O_2\text{max}}$ ≥15 mL/kg/min
$V_{O_2\text{max}}$ <15 mL/kg/min
Cleared for pneumonectomy
High risk for pneumonectomy
Calculate predicted postlobectomy FEV_1 and DL_{CO}
Predicted postlobectomy FEV_1 and DL_{CO} ≥40% of predicted normal
Predicted postlobectomy FEV_1 and DL_{CO} <40% of predicted normal
Cleared for lobectomy
High risk for lobectomy

*If CPET is unavailable, consider stair climbing or shuttle walk testing as alternatives.

Figure 102-3 Algorithm for preoperative evaluation for lung resection. See text for discussion. DOE, dyspnea on exertion; ILD, interstitial lung disease.

postoperative pulmonary morbidity and mortality.[193] Although data on preoperative preparation are limited, for patients with active obstructive airway disease, intensive preoperative respiratory therapy (bronchodilators, corticosteroids, antibiotics, and chest physiotherapy) does appear to reduce the incidence of postoperative respiratory complications by more than 50%.[93,194–196]

Several preoperative prophylactic measures should be considered in patients undergoing elective surgery (Table 102-8).

Pulmonary function in patients with obstructive airway disease should be optimized. Therapy may include any or all of the following: bronchodilators, corticosteroids, antibiotics (when there is evidence of infection), and chest physiotherapy (if excessive secretions are present). When possible, these interventions should be implemented 48 to 72 h prior to surgery.

TABLE 102-8 Preoperative Pulmonary Preparation

Optimization of airway function in patients with obstructive lung disease (bronchodilators; corticosteroids, antibiotics, and chest physiotherapy when indicated)
Smoking cessation (ideally a minimum of 8 weeks prior to surgery)
Patient education (deep breathing exercises, importance of coughing and pain control, use of incentive spirometry)
Consider inspiratory muscle training

Reproduced with permission from Goldmann DR, Brown FH, Guarnieri DM: Perioperative Medicine. New York, NY: McGraw Hill; 1994.

Ideally, for at least 8 weeks prior to surgery, smoking should be discontinued. As noted previously, data indicate that complication rates are not increased by shorter periods of abstinence; therefore, even when 8 weeks of abstinence is not possible, patients should still be advised to quit smoking prior to surgery.[90,91]

A program of inspiratory muscle training for at least 2 weeks prior to surgery may reduce the incidence of postoperative pulmonary complications in patients at high risk for their development.[197]

Finally, patient education on the importance of postoperative coughing and pain control, proper use of an incentive spirometer, and deep breathing exercises should take place preoperatively.

POSTOPERATIVE PROPHYLACTIC MEASURES

Several postoperative measures may be employed in an attempt to prevent respiratory complications (Table 102-9).

Early patient mobilization and ambulation should be encouraged. As noted previously, these measures are important postoperatively in reducing the incidence of atelectasis, in promoting the clearance of secretions, and in decreasing the risk of thromboembolic disease.

Prophylactic lung expansion maneuvers should be initiated.[198,199] Two equally effective measures are deep breathing exercises and incentive spirometry.[200,201] Intermittent positive pressure breathing

TABLE 102-9 Postoperative Measures for the Prevention of Respiratory Complications

Early patient mobilization and ambulation
Prophylactic lung expansion maneuvers (incentive spirometry, deep breathing exercises, CPAP)
Provision of adequate analgesia
Prophylaxis against thromboembolism

Reproduced with permission from Goldmann DR, Brown FH, Guarnieri DM: Perioperative Medicine. New York, NY: McGraw Hill; 1994.

(IPPB) is generally ineffective and costly and is associated with several adverse effects.[198,199] Reports of intermittent continuous positive airway pressure (CPAP) applied by face mask indicate that it is at least equivalent to deep breathing exercises and incentive spirometry in preventing atelectasis and pneumonia.[202] However, while CPAP may be useful in the patient who cannot cooperate with inspiratory maneuvers, its role in the management of patients capable of taking deep breaths is unclear.

Adequate analgesia should be provided, particularly for patients undergoing major, open surgery. Traditionally, parenteral narcotics have been used for postoperative analgesia, despite the risk of respiratory depression. Unfortunately, concerns over adverse respiratory effects may lead to inadequate dosing and inadequate pain relief. To overcome this problem, alternative approaches, including use of epidural analgesia, peripheral nerve blockade, paravertebral block, and wound catheter infiltration may be employed as alternatives to the use of systemic opioids.[203] These alternative techniques provide analgesia equivalent or superior to parenteral narcotics; however, whether they are effective in reducing postoperative pulmonary complications remains unclear.

Prophylaxis for thromboembolism is an important consideration,[204] and careful monitoring for other postoperative complications constitutes a key element in all surgical patients.

Finally, several postoperative interventions have been shown to be ineffective, including chest physiotherapy in the absence of excessive secretions or sputum production,[205] and routine application of positive end-expiratory pressure in mechanically ventilated patients.[206]

CHAPTER 103

Acute Respiratory Failure in the Surgical Patient

Robert M. Kotloff

INTRODUCTION

Advances in surgical technique, anesthesia and analgesia, and postoperative supportive care have emboldened surgeons to consider an expanding spectrum of patients for surgical interventions. In most instances, the success or failure of the surgery is defined not in the operating room, but postoperatively, when the adverse effects of surgery may first become apparent and when intercurrent complications may jeopardize the patient's recovery. The respiratory system is particularly vulnerable to the effects of general anesthesia and surgery, and postoperative respiratory impairment is common. While generally mild and well tolerated in otherwise healthy, young patients, postoperative respiratory compromise may have serious consequences in the elderly and in patients with preexisting lung disease. A number of postoperative complications, such as pneumonia, aspiration pneumonitis, and acute respiratory distress syndrome (ARDS) may lead to respiratory compromise independent of the patient's pre-surgical status.

This chapter focuses on the most serious consequence of perioperative respiratory compromise—acute respiratory failure. This complication is associated with a 30-day mortality rate in the range of 25% following major surgical procedures, compared to approximately 1% for unaffected patients.[1,2] In addition to its adverse impact on survival, respiratory failure prolongs intensive care and hospital stay, delays convalescence, and increases health care costs among survivors. Clinicians who provide preoperative evaluation and postoperative care must be able to identify high-risk patients who require a greater degree of vigilance, and to rapidly recognize and appropriately treat the complications that result in postoperative respiratory failure.

ASSESSING THE RISK OF POSTOPERATIVE RESPIRATORY FAILURE

Several calculators have been developed to estimate the risk of postoperative respiratory failure. All were constructed based on data derived from large national databases, but, notably, none has been externally validated. Furthermore, these calculators share a common definition of postoperative respiratory failure as mechanical ventilation beyond the initial 48 h following surgery or need for reintubation. This definition fails to distinguish patients requiring what most physicians (and patients) would consider to be an acceptable period of limited postoperative ventilatory support from those who truly would require prolonged ventilatory support and its attendant risks and complications. Arozullah et al. developed the first major calculator to focus specifically on respiratory failure, utilizing a database of more than 81,000 cases from 44 Veterans Affairs (VA) hospitals in their derivation cohort.[3] Respiratory failure developed in 3.4%. The type of surgical procedure was the strongest independent predictor of postoperative respiratory failure; those with the highest odds ratio for developing respiratory failure included abdominal aortic aneurysm repair, thoracic surgery, upper abdominal surgery, and neurosurgical procedures. Other independent variables included in the derived risk calculator were emergency surgery, albumin <3.0 mg/dL, blood urea nitrogen >30 mg/dL, partially or fully dependent functional status, history of chronic obstructive pulmonary disease (COPD), and age 60 or greater. Points assigned to each of these parameters are shown in Table 103-1, and the predicted risk of respiratory failure based on cumulative points is shown in Table 103-2. The generalizability of this risk calculator is limited by the exclusively male population, the high prevalence of comorbidities that typically characterizes a VA cohort, and the exclusion of cardiac surgery.

TABLE 103-1 Arozullah Respiratory Failure Risk Calculator Point System

Preoperative Predictor	Point Value
Type of surgery	
Abdominal aortic aneurysm	27
Thoracic	21
Neurosurgery, upper abdominal, peripheral vascular	14
Neck	11
Emergency surgery	11
Albumin <3 g/dL	9
Blood urea nitrogen >30 mg/dL	8
Partially or fully dependent functional status	7
History of COPD	6
Age (years)	
≥ 70	6
60–69	4

In an attempt to render their model more broadly applicable, Johnson et al. published an updated predictive model based on cases derived from both VA hospitals and private academic centers and that included 20% women.[1] Twenty-eight variables were identified to be independently associated with increased risk and were assigned point values based on their associated odds ratio for

TABLE 103-2 Arozullah Respiratory Failure Risk Calculator Predictions

Point Total	Predicted Probability of Respiratory Failure
≤ 10	0.5%
11–19	2.2%
20–27	5.0%
28–40	11.6%
>40	30.5%

Data from Arozullah AM, Daley J, Henderson WG, et al. Multifactorial risk index for predicting postoperative respiratory failure in men after major noncardiac surgery. The National Veterans Administration Surgical Quality Improvement Program. Ann Surg. 2000;232(2):242–253.

respiratory failure (Table 103-3). Similar to their previous model, the type of procedure influenced risk, with the greatest incidence of respiratory failure associated with upper aerodigestive tract surgery, thoracic or thoracoabdominal aneurysm repair, thoracic surgery, and gastrointestinal and hepatobiliary surgery. A steady rise in risk of respiratory failure was documented with cumulative scores above 12 (Fig. 103-1). Unfortunately, the complexity of the model renders it unwieldy and has limited its widespread acceptance. Like the earlier model, it also cannot be applied to cardiac surgery patients.

TABLE 103-3 Johnson Respiratory Failure Risk Calculator: Parameters Used and Score Assigned

Parameter Set	Description	Score
1	ASA class 3	3
1	ASA class 4–5	5
2	Emergency	2
3	Work RVU 10–17	2
3	Work RVU >17	4
4	Preoperative albumin ≤3.5	1
5	Procedure: Integumentary	1
5	Procedure: Respiratory and hemic	3
5	Procedure: Heart	2
5	Procedure: Aneurysm	2
5	Procedure: Mouth, palate	7
5	Procedure: Stomach, intestines	2
5	Procedure: Endocrine	2
6	Preoperative sepsis	2
7	Preoperative creatinine ≥1.5	2
8	History of severe COPD	2
9	Ascites	2
10	Dyspnea	1
11	Impaired sensorium	1
12	Preoperative bilirubin >1.0	1
13	>2 alcoholic drinks/d in 2 weeks before admission	1
14	Bleeding disorders	1
15	Age >40 y	2
16	Preoperative white blood count <2.5 or >10	1
17	Preoperative serum sodium >145	2
18	Weight loss >10%	1
19	Preoperative acute renal failure	2
20	Male gender	1
21	Congestive heart failure <30 d before operation	1
22	Smoker	1
23	Preoperative platelet count ≤150	1
24	CVA/stroke with neurologic deficit	1
25	Wound class (clean/contaminated)	1
25	Wound class (contaminated)	1
25	Wound class (infected)	1
26	Preoperative AST >40	1
27	Preoperative hematocrit ≤38	1
28	CVA/stroke without neurologic deficit	1

ASA, American Society of Anesthesiologists; COPD, chronic obstructive pulmonary disease; CVA, cerebrovascular accident; RVU, relative value unit.
Data from Johnson RG, Arozullah AM, Neumayer L, et al. Multivariable predictors of postoperative respiratory failure after general and vascular surgery: results from the patient safety in surgery study. J Am Coll Surg. 2007;204(6):1188–1198.

In one of the larger studies to date, Gupta et al. used the 2007 American College of Surgeons National Surgical Quality Improvement Program (NSQIP) database of more than 210,000 patients who underwent a broad array of surgical procedures, including cardiac surgery.[2] On multivariate logistic regression analysis, five preoperative predictors of postoperative respiratory failure were identified: type of surgery (highest risk with brain, abdominal, aortic surgery), emergency cases, poor preoperative functional status, preoperative sepsis, and higher ASA class. These variables were incorporated into a predictive model that was validated in a second cohort of more than 250,000 patients from the 2008 NSQIP database. An interactive risk calculator, available at *www.surgicalriskcalculator.com/prf-risk-calculator*, was then developed to estimate the likelihood of respiratory failure for a given patient.

Pulmonary consultants providing preoperative assessment are commonly asked to specifically comment on the risk posed by a patient's history of COPD. COPD has been identified as an independent predictor of postoperative respiratory failure in numerous studies.[1,4–8] The largest and most comprehensive study utilized the NSQIP database containing more than 460,000 patients who underwent a variety of surgical procedures.[7] COPD was independently associated with an increased risk of ventilator dependence for more than 48 h following surgery (odds ratio [OR], 1.45) and reintubation (OR, 1.54). Notably, neither this study nor the others referenced above categorized patients according to preoperative pulmonary function parameters, precluding conclusions about the relationship between severity of COPD and risk of postoperative respiratory failure.

The use of preoperative pulmonary function testing to assess risk of postoperative respiratory failure in COPD patients has been most closely examined in the context of lung resection surgery for lung cancer. Studies of patients undergoing standard thoracotomy and either pneumonectomy or lobectomy have used preoperative spirometry in conjunction with quantitative ventilation/perfusion lung scans to estimate post-resection FEV_1 and diffusing capacity. While the study populations are small, published case series suggest that a predicted post-resection FEV_1 or diffusing capacity less than 40% of normal is associated with a high risk for postoperative respiratory failure and death.[9–12] In one study that examined the performance characteristics of these parameters, the probability of respiratory failure or death was 33% for those patients with an FEV_1 <40% while the probability of avoiding these complications was 90% for those with an FEV_1 ≥40%.[11] Coupling pulmonary function testing with cardiopulmonary exercise testing allows for more precise risk stratification. Those patients with peak oxygen consumption of ≥10 to 15 mL/kg/min despite predicted post-resection FEV_1 or diffusing capacity <40% appear to have a low risk of respiratory failure and death following thoracotomy and definitive lung resection procedures.[10,13] The use of video-assisted thoracoscopic surgery (VATS) in combination with lobectomy, segmentectomy, or wedge resection appears to be well tolerated by patients with severe lung disease, with only a 4% incidence of respiratory failure and a 1% mortality rate documented in one study of 100 consecutive patients with an FEV_1 <35% predicted.[14]

Studies using preoperative spirometry to assess severity of COPD in patients undergoing cardiac surgery have provided conflicting results with respect to the risk of respiratory failure. One study found that an FEV_1 <70% was an independent predictor of respiratory failure after coronary artery bypass graft (CABG), but the rather broad nature of the spirometric threshold used limits the

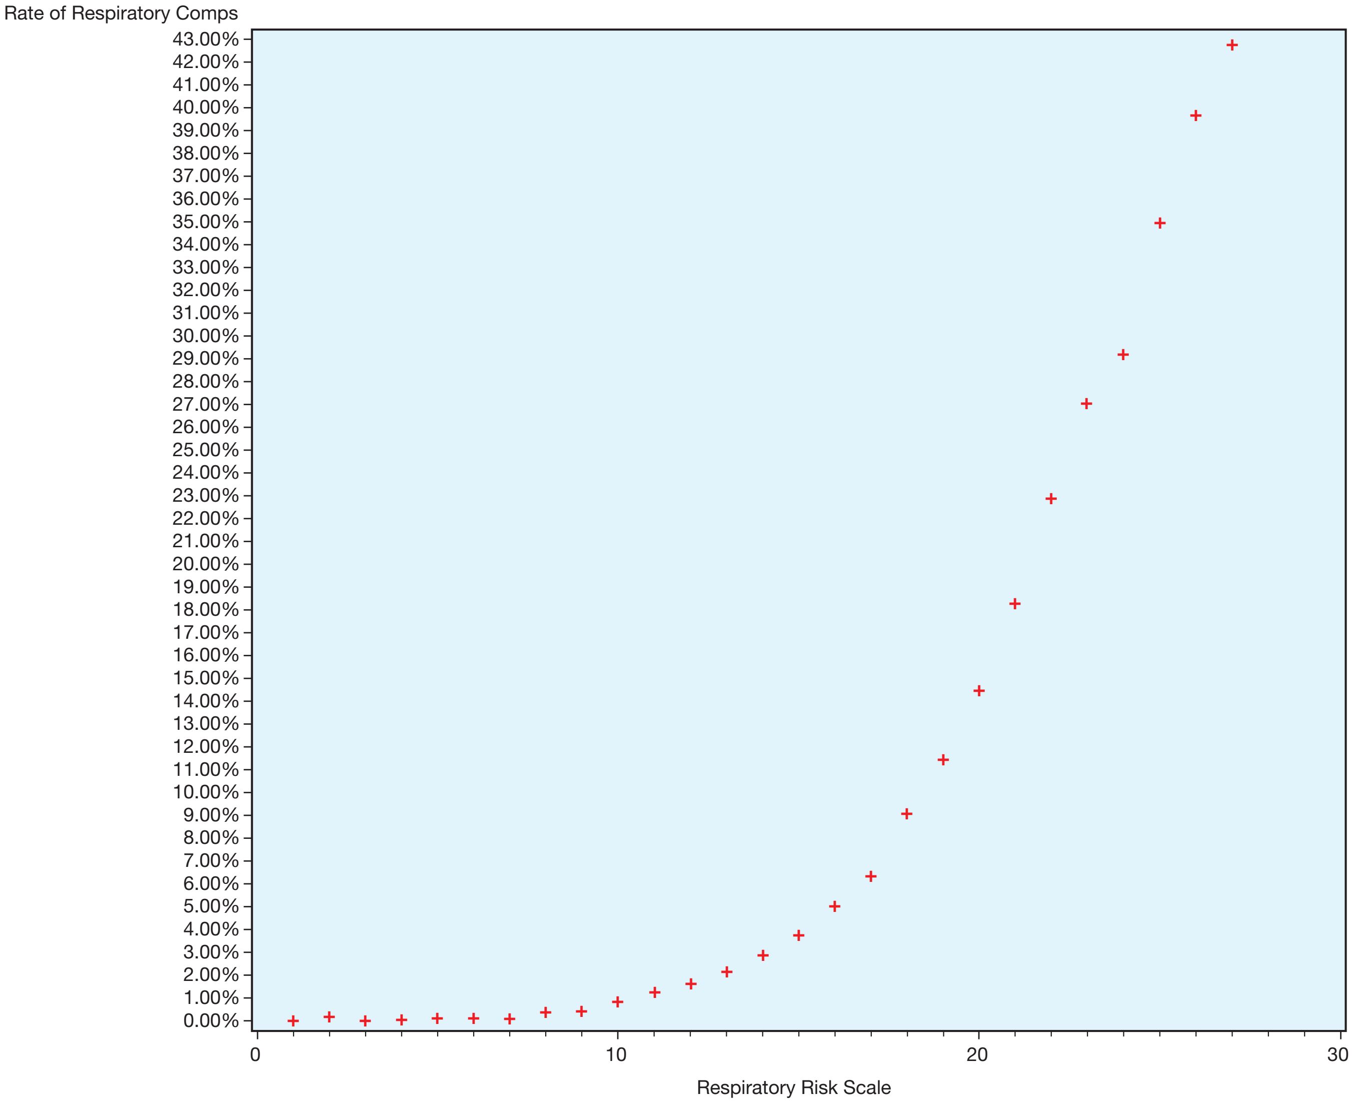

Figure 103-1 Johnson Respiratory Failure Risk Calculator. This graph plots the predicted risk of respiratory failure on the y axis against the respiratory risk score on the x axis. *(Reproduced with permission from Johnson RG, Arozullah AM, Neumayer L, et al. Multivariable predictors of postoperative respiratory failure after general and vascular surgery: results from the patient safety in surgery study. J Am Coll Surg. 2007;204(6):1188–1198.)*

utility of this finding.[4] A study of 1412 patients found that the combined incidence of prolonged postoperative mechanical ventilation (>48 h) and reintubation increased with increasing severity of COPD: 2.3% in patients without COPD compared to 0%, 13%, and 77% in patients with FEV_1 60% to 80%, 40% to 59%, and <40%, respectively. In contrast, the largest study to date utilizing a database of more than 11,000 patients did not detect an association between COPD severity and risk of prolonged postoperative mechanical ventilation even among patients with the most severe disease (FEV_1 <50%), although there was an increased risk of early mortality in this group.[15]

Data related to the use of preoperative pulmonary function parameters to stratify risk of postoperative respiratory failure in relation to noncardiothoracic surgical procedures are scant and conflicting. These data are summarized in a guideline statement issued by the American College of Physicians, which concludes that for noncardiothoracic surgery, "insufficient evidence supports preoperative spirometry as a tool to stratify risk."[16] The guideline authors caution that available studies do not define a spirometric threshold below which the risk for noncardiothoracic surgery is prohibitive.

MEASURES TO REDUCE RISK

A number of the factors associated with an increased risk of postoperative respiratory failure can potentially be addressed in order to mitigate the risk. In some cases, the surgical approach can be modified. For example, use of a transverse abdominal incision appears to carry less risk than a vertical midline incision. Cholecystectomy performed by laparoscopic technique is associated with significantly less compromise in postoperative FEV_1 and FVC and more rapid recovery of lung function compared with the conventional open approach.[17] For thoracic procedures, median sternotomy and muscle-sparing lateral thoracotomy are better tolerated than posterolateral thoracotomy. However, these approaches provide more limited access to the thorax than does the standard thoracotomy incision and they are generally inadequate for resection of the left lower lobe or for tumors involving the posterior chest wall, diaphragm, or superior sulcus. Additionally, removal of bulky tumors via the muscle-sparing approach may be problematic. VATS offers a minimally invasive alternative that is associated with a less severe decrement in respiratory muscle strength and lung function in the immediate perioperative period compared to thoracotomy.[18] A propensity-matched analysis of patients undergoing lobectomy by means of VATS versus open thoracotomy demonstrated a significantly lower rate of postoperative reintubation in the VATS cohort (1.4% vs. 3.1%).

Patients with COPD scheduled for surgery should undergo a preparatory pulmonary regimen intended to optimize lung function and minimize airway secretions. This regimen should include smoking cessation, institution or intensification of inhaled bronchodilator therapy, and use of oral antibiotics in the presence of purulent secretions or a "loose" cough. Patients should be instructed on the use of incentive spirometry or cough and deep breathing techniques prior to surgery. A short course of oral corticosteroids should be considered in patients who have a significant bronchospastic component to their disease. Other than the assurance of strict compliance with the regimen, there is no reason to believe that hospitalization is superior to outpatient preparation of the patient.

Smoking has been shown to be a risk factor for postoperative pulmonary complications in general and for prolonged ventilatory support in particular.[1] Smoking does not appear simply to be a surrogate marker of COPD; rather it poses risk that is independent of the magnitude of pulmonary impairment. Detrimental effects of smoking include bronchial irritation with resultant excessive airway secretions, impairment in mucociliary clearance, and elevation of carboxyhemoglobin levels with consequent impairment in oxygen uptake and tissue oxygen utilization. Observational studies suggest that preoperative smoking cessation is associated with a reduction in pulmonary complications, but these studies do not address the specific question of whether abstinence reduces the risk of respiratory failure.[19] A prospective, randomized trial investigated the impact of a preoperative smoking cessation program (counseling and nicotine replacement patch) on a number of postoperative complications including respiratory failure, following elective hip and knee replacement. Complete abstinence from smoking was achieved in 60% of the patients in the intervention arm compared with only 7% in the control arm. Despite this marked difference, only one patient in each group experienced postoperative respiratory failure. The obvious limitation of this trial relates to the choice of a surgical population at minimal risk for the complication under investigation. Pending additional studies, it would appear prudent to initiate smoking cessation measures in preparing patients for surgery, although the full benefit with respect to global reduction in pulmonary complications may require a minimum of 8 weeks of abstinence.[20]

IMPACT OF ANESTHESIA AND POSTOPERATIVE ANALGESIA ON PULMONARY FUNCTION

In the sections below, the impact of anesthesia and postoperative analgesia on pulmonary function is considered with regard to general anesthesia and neuraxial and postoperative analgesia.

General Anesthesia

Use of general anesthetic agents is associated with a number of well-characterized alterations in pulmonary mechanics, gas exchange, and respiratory drive.[21,22] In the controlled environment of the operating room, these physiologic derangements are clinically inconsequential and easily overcome by simple adjustments of the ventilator. However, lingering effects of general anesthesia after completion of surgery may impede efforts to extubate the patient or may precipitate respiratory failure in the recovery room.

Administration of general anesthesia, whether by the inhaled or intravenous route, results in an almost immediate loss of diaphragmatic and intercostal muscle tone, a cephalad shift of the diaphragm, and a decrease in the transverse thoracic diameter. These dimensional alterations in thoracic volume result in a 20% reduction in functional residual capacity (FRC) and in the development of compressive atelectasis. As demonstrated using computerized tomography (CT) during and after general anesthesia, patients develop crescent-shaped areas of atelectasis in dependent areas of lung within 10 min of induction.[23] Atelectatic areas constitute approximately 2% to 10% of total lung volume and disappear with the application of positive end-expiratory pressure (PEEP). Dependent atelectasis develops after administration of either inhalational or intravenous anesthetics. A notable exception is ketamine, a drug that is unique in its maintenance of respiratory muscle tone. The degree of atelectasis appears unaffected by whether the patient is breathing spontaneously or is mechanically ventilated.

Areas of dependent atelectasis perturb the normal balance of ventilation and perfusion in the lung. Persistent perfusion of nonventilated atelectatic areas results in an increase in the shunt fraction, which may approach 15%. The magnitude of shunt correlates directly with the volume of atelectatic lung and may be further magnified by impairment of hypoxic pulmonary vasoconstriction induced by certain inhalational anesthetics. Elderly patients, those who are obese, and patients with underlying COPD are most likely to develop clinically apparent hypoxemia in response to general anesthesia; the effect may persist into the early postoperative period.

The inhaled anesthetic agents in common usage are respiratory depressants that blunt the response to both hypoxemia and hypercapnia. These agents depress the ventilatory response to CO_2 in a dose-dependent fashion. They have a negligible effect on the hypercapnic response at the low concentrations encountered during emergence from anesthesia. In contrast, hypoxemic drive is markedly attenuated even at very low, subanesthetic concentrations of the volatile agents. As a result of deposition of these agents in muscle and fat, concentrations sufficient to depress hypoxic drive persist for several hours after termination of anesthesia. This can result in significant postoperative respiratory depression in patients with chronic hypercapnia who are dependent on hypoxic ventilatory drive to breathe.

Neuromuscular blocking agents are commonly administered intraoperatively along with general anesthesia. Although reversing agents are administered at the completion of surgery, between 33% and 64% of postsurgical patients arriving in the postanesthesia care unit have inadequate neuromuscular recovery as assessed by train-of-four monitoring.[24] Studies in normal volunteers have demonstrated that residual neuromuscular blockade is associated with marked attenuation of hypoxic ventilatory response, reduced upper airway dilator muscle activity, and impaired respiratory muscle strength.[24] Likely as a consequence of these effects, an association of residual neuromuscular blockade with postoperative hypoxemia and with upper airway obstruction has been shown.[24–26]

Neuraxial Anesthesia

It is common practice for those providing preoperative assessment of high-risk patients to recommend the use of neuraxial (i.e., spinal or epidural) anesthesia, predicated on the impression that this route of administration lessens the adverse impact of anesthesia on the respiratory system. Neuraxial anesthesia does possess a number of favorable physiologic features. In contrast to the effects of general anesthesia, neuraxial anesthesia preserves diaphragmatic innervation and function. External intercostal muscle paralysis is induced by thoracic levels of neuraxial anesthesia, but the level is generally two dermatomes below the sensory level because of the lesser sensitivity of motor neurons to the effects of the anesthetic agent. Hypoxic pulmonary vasoconstriction is unaffected by neuraxial anesthesia, and the ventilatory response to CO_2 is unimpaired; indeed, the CO_2 response may be heightened. A meta-analysis of trials comparing general to neuraxial anesthesia detected a significant reduction in 30-day mortality, venous thromboembolism, pneumonia, and respiratory depression.[27] Another meta-analysis restricted to patients undergoing hip fracture surgery also detected a reduction in 30-day mortality as well as a trend toward a lower incidence of postoperative hypoxemia associated with neuraxial anesthesia.[28] While these analyses suggest significant advantages associated with use of neuraxial anesthesia, they have been criticized because of the heterogeneous nature of the surgical populations and the use of older anesthetic techniques and older anesthetic agents.[29] Pending further studies, neuraxial anesthesia should not necessarily be viewed as the strategy of choice in more tenuous surgical candidates.

■ Postoperative Analgesia

Postoperative analgesia is an essential component of the care of the surgical patient. Analgesia is important not only in ensuring patient comfort, but also in mitigating the adverse effects of pain on respiratory function and airway clearance. Inadequate pain relief can lead to splinting and patient reluctance to cough and deep breathe; the end result is promotion of retained secretions, atelectasis, hypoxemia, and, possibly, pneumonia. For major surgical procedures, particularly those involving the chest and upper abdomen, administration of opiates via the parenteral or epidural route has become the analgesic method of choice.

The use of narcotic analgesia in the postoperative period is associated with a small but not insignificant risk of precipitating respiratory depression. The reported incidence of respiratory depression varies based on the criteria employed. A meta-analysis of published studies revealed an incidence of 0.3% defined by the need to administer naloxone, 3.3% defined by the presence of hypercapnia, and 17% defined by oxygen desaturation.[30] The risk may be slightly lower in association with the epidural as opposed to parenteral route of administration. When administered epidurally, hydrophilic narcotics (e.g., morphine) have a greater tendency than lipophilic compounds (e.g., fentanyl) to remain in the cerebrospinal fluid and to spread rostrally to the respiratory center located in the floor of the fourth ventricle. Elderly patients are particularly susceptible to the respiratory depressant effects of opiates, likely reflecting an impaired ability to metabolize these agents. Respiratory depression in the postoperative patient is most likely to occur during the initial 24 h following surgery. It is typically accompanied by a decreased level of consciousness and a slow respiratory rate. Treatment consists of administration of naloxone in 0.1- to 0.4-mg aliquots. Ventilation should be supported with a facemask and Ambu bag, reserving intubation for the failure of naloxone to swiftly rectify the problem.

Prospective, randomized trials examining pulmonary complications associated with epidural versus intravenous administration of perioperative analgesia following major abdominal surgical procedures have provided somewhat conflicting results. One study of 168 patients found no difference in rates of prolonged intubation or reintubation between groups receiving epidural versus intravenous postoperative analgesia.[31] A small trial involving 70 elderly patients reported no difference in duration of postoperative mechanical ventilation or major pulmonary complications (including reintubation).[32] In contrast, a larger study of 915 patients with at least one comorbidity defining them as "high-risk" surgical candidates found that epidural analgesia was associated with a significant reduction (23% with epidural vs. 30% with intravenous route) in postoperative respiratory failure, defined rather broadly as need for prolonged ventilation or reintubation or $Pa_{O_2} \leq 50$ mm Hg or $Pa_{CO_2} \geq 50$ mm Hg on room air.[33] Finally, a trial of more than 1000 patients demonstrated a significant reduction in postoperative respiratory failure (defined as the need for intubation and mechanical ventilation for >24 h postoperatively or reintubation) with use of epidural analgesia in the subset of patients undergoing aortic surgery but not those undergoing non-aortic abdominal surgery.[34]

IMPACT OF SURGERY ON POSTOPERATIVE PULMONARY FUNCTION

Surgery involving the upper abdomen and thorax results in a pronounced impairment in pulmonary function in the postoperative period. The impairment is more severe and prolonged than that due to administration of general anesthesia alone. Typically, upper abdominal and thoracic procedures are associated with a fall in lung volumes, development of atelectasis, and hypoxemia. These adverse effects commonly necessitate short-term administration of low-flow, supplemental oxygen, but when severe, or when accompanied by underlying lung disease, may precipitate respiratory failure.

■ Upper Abdominal Surgery

Within 24 h following upper abdominal surgery, vital capacity declines by 50%.[35] Although the vital capacity improves with time, marked impairment persists for as long as 7 days after the surgery. In contrast, vital capacity falls by only 25% following lower abdominal procedures; it returns to normal by the third postoperative day.[35] Underlying these profound changes after upper abdominal surgery is the development of diaphragmatic dysfunction, as reflected in a reduction in transdiaphragmatic pressure with tidal respirations and in a shift from abdominal to rib cage breathing.[36,37]

Two main theories have been proposed to explain the observed impairment in diaphragmatic function. One theory is that there is a primary alteration in diaphragmatic contractility induced by local irritation, inflammation, surgical trauma, or pain. This theory has been rendered improbable with the demonstration that external stimulation of the phrenic nerves produces normal peak transdiaphragmatic pressure in patients recovering from upper abdominal surgery.[36] In other words, when maximally stimulated the diaphragm functions in a normal fashion.

The alternative, and currently favored, theory proposes that diaphragmatic dysfunction results from diminished phrenic nerve output. The basis for the attenuation in neural drive remains a matter of speculation, although several putative pathways can be rationally eliminated. For example, general anesthesia is known to depress output from the central respiratory centers, as well as to inhibit synaptic transmission. However, as noted previously, the effects of general anesthesia on diaphragmatic tone are transient and modest. Additionally, the degree of dysfunction observed after upper abdominal procedures is not seen following general anesthesia for procedures on the lower abdomen and extremities. An inhibitory arc initiated by abdominal nociceptors for pain is unlikely, given that achievement of adequate pain control by epidural opiates fails to consistently improve pulmonary function or to normalize diaphragmatic performance. In contrast, the epidural administration of anesthetic agents such as bupivacaine does ameliorate diaphragmatic dysfunction following upper abdominal surgery. Since these agents produce sympathetic blockade in addition to pain control, it has been argued that visceral sympathetic afferents are responsible for providing an inhibitory signal that downgrades central neural drive and phrenic nerve activity, thereby leading to impaired diaphragmatic function. Supporting the notion of a reflex inhibitory arc mediated by visceral afferents is the demonstration in experimental animals that mechanical gall bladder stimulation strongly inhibits electromyographic activity and motion of the diaphragm.[38]

■ Cardiac Surgery

Although CABG—the most commonly performed cardiac surgical procedure—has been most intensively scrutinized with respect to its impact on the respiratory system, other related cardiac procedures (e.g., valve replacement) are likely to have similar effects. Lung volumes decrease by approximately 30% after CABG; the return to preoperative values may take several months.[39–41] Lung function may decline to a greater degree when internal mammary harvesting and grafting are employed.[39] Gas exchange is also impaired after CABG, as evident in the development of hypoxemia and significant widening of the alveolar–arterial oxygen gradient. In 125 patients who had daily room air arterial blood gas determinations prior to and following CABG, Pa_{O_2} fell from approximately 75 mm Hg preoperatively to a nadir of 55 mm Hg on postoperative day two.[42] The Pa_{O_2} improved but remained below preoperative values at the end of the first postoperative week. A similar pattern and magnitude of decline in oxygenation have been demonstrated in other studies, with the development of hypoxemia associated with an increase in calculated shunt fraction from 3% preoperatively to a peak of 19% postoperatively.[41] The increase in shunt fraction is readily accounted for on the basis of atelectasis, which is invariably present postoperatively, especially on the left side.

A number of factors have been implicated in the development of post-CABG pulmonary dysfunction and atelectasis. Alterations in chest wall compliance and motion may result from division of the sternum, harvesting of the internal mammary artery, and traumatic injury to the costovertebral joints and first rib induced by retraction. Intraoperative lung retraction may directly injure the left lower lobe, leading to contusion and atelectasis, and, perhaps, accounting for the predilection for radiographic infiltrates on the left side. An alternative explanation for post-CABG left lower lobe atelectasis is intraoperative injury to the left phrenic nerve and consequent diaphragmatic paralysis or paresis. The phrenic nerve is vulnerable to stretch and ischemic injury during sternal retraction, dissection of the left internal mammary artery, or prolonged distention of the pericardium. Additionally, thermal injury to the nerve may occur with the cardioplegic technique of instilling iced slush into the open pericardial sac. The actual incidence of phrenic nerve dysfunction after CABG is best defined in studies employing electrophysiologic techniques, which have documented evidence of phrenic nerve injury in 10% to 16% of patients.[43–45] This suggests that phrenic nerve injury accounts for only a minority of the observed cases of left lower lobe atelectasis.

Finally, cardiopulmonary bypass (CPB) may contribute to pulmonary impairment after cardiac surgery. The duration of CPB has been linked to the severity of postoperative atelectasis; whether this relationship is causal is unclear.[44] It has been hypothesized that the use of CPB leads to abnormal surfactant production—possibly due to ischemic, thermal, or toxic injury to the alveolar epithelium—predisposing to the development of atelectasis. More clearly established is the ability of the bypass pump to induce a capillary leak syndrome, marked by extravasation of fluid into the alveolar interstitium and, rarely, into the airspaces. This process is thought to result from exposure of blood to nonendothelial surfaces, resultant activation of neutrophils, complement, and other inflammatory cascades, and sequestration of neutrophils within the microvasculature. While this rarely may lead to full-blown ARDS (see "Acute Respiratory Distress Syndrome," below), the consequences are usually more subtle, manifesting as a widened arterial–alveolar oxygen gradient and diminished lung compliance. The recent introduction of "off-pump" CABG has permitted a greater appreciation of the adverse impact of CPB on postoperative lung function. For example, a large multicenter comparative analysis from the United Kingdom of CABG with or without CPB demonstrated significant reductions in the rates of prolonged mechanical ventilation (>24 h), reintubation/tracheostomy, and ARDS/pulmonary edema/pneumonia among the group that underwent off-pump CABG.[46]

■ Lung Resection

Unique to lung resection surgery is the immediate loss of lung function due to removal of lung parenchyma. The magnitude of the loss can be estimated reliably from preoperative quantitative lung scanning in conjunction with standard spirometry. The impact of lung resection on pulmonary function is further magnified in the perioperative period by other factors. For example, the standard posterolateral thoracotomy incision represents significant chest wall trauma, with rib retraction and resection, and transection of intercostal, latissimus dorsi, trapezius, and serratus anterior muscles. As a result, total respiratory compliance may fall by as much as 75%; work of breathing increases; and lung volumes decline dramatically, out of proportion to the surgical loss of functional lung. Following standard thoracotomy and lung resection (either lobectomy or wedge resection), FEV_1 and FVC fall to 25% of preoperative values at 1 h, and to 30% to 40% at 24 h.[47,48] When a more limited, muscle-sparing incision is used, the impact on pulmonary function is markedly attenuated.[48] Lung resection via VATS is also associated with less severe impairment in lung function.[18]

As with cardiac and upper abdominal surgery, atelectasis is frequently present after lung surgery and results in impaired oxygenation. Phrenic nerve activity remains normal and diaphragmatic function during tidal breathing is preserved, although maximal diaphragmatic strength may be reduced.

CAUSES OF POSTOPERATIVE RESPIRATORY FAILURE

The development of acute respiratory failure in the surgical patient should prompt a systematic assessment of the likely causes (Table 103-4). In approaching this life-threatening problem, one must consider the nature and magnitude of pre-existing pulmonary disease, type of surgery performed, drugs administered intra- and postoperatively, and predominant derangement in gas exchange (i.e., hypoxemia or hypercapnia). In conjunction with important information derived from the physical examination and chest radiograph, the analysis should readily identify factors responsible for or contributing to respiratory failure. The following discussion focuses on the more common or unique causes of postoperative respiratory failure in the surgical setting.

■ Atelectasis

Atelectasis is the most common pulmonary complication encountered in the surgical patient, particularly following thoracic and upper abdominal procedures. As discussed previously, anesthesia and surgical manipulation act in concert to produce regional atelectasis through incompletely defined mechanisms, including diaphragmatic dysfunction and diminished surfactant activity. The atelectasis is typically basilar and segmental in distribution,

TABLE 103-4 Causes of Postoperative Respiratory Failure

Factors extrinsic to the lung
- Depression of central respiratory drive (anesthetics, opioids, sedatives)
- Phrenic nerve injury/diaphragmatic dysfunction
- Obstructive sleep apnea

Factors intrinsic to the lung
- Atelectasis
- Pneumonia
- Aspiration of gastric contents
- Acute respiratory distress syndrome
- Volume overload/congestive heart failure
- Pulmonary embolism
- Bronchospasm/COPD

obscuring the hemidiaphragms radiographically. A distinct and less common cause of postoperative atelectasis is plugging of central airways by retained secretions. This problem is encountered in the surgical patient whose efforts to clear secretions are compromised by depressed consciousness, inadequate pain control, or a weak, ineffective cough. When situated in a mainstem bronchus, mucus plugs can result in collapse of an entire lung; more distal obstruction leads to lobar collapse. An abrupt termination of the proximal bronchial air shadow and the absence of air bronchograms within the atelectatic portion of lung are clues to the possible presence of mucus plugging.

While often clinically insignificant, postoperative atelectasis may lead to severe hypoxemia and respiratory distress. The magnitude of hypoxemia is dictated by the extent of atelectasis, the presence and severity of underlying lung disease, and the integrity of the hypoxemic pulmonary vasoconstrictive response. Impairment of hypoxemic pulmonary vasoconstriction by vasodilatory drugs, commonly administered to surgical patients for treatment of underlying hypertension or ischemic heart disease, prevents the compensatory diversion of blood flow away from nonventilated areas of lung and magnifies the shunt fraction.

Respiratory distress due to atelectasis usually evolves insidiously over the first several postoperative days. Supplemental oxygen requirements increase in association with worsening basilar infiltrates noted on the chest radiograph. The clinicoradiographic picture may be indistinguishable from that of pneumonia. While fever and leukocytosis suggest infection, these signs are common and nonspecific. When atelectasis is due to central airway occlusion by mucus plugs, hypoxemia and respiratory distress may develop quickly. A chest radiograph obtained immediately after the onset of symptoms may be surprisingly unrevealing if sufficient time has not passed to permit resorption of gas from the air spaces of the nonventilated lung. Careful examination of the patient, however, will reveal an absence of breath sounds over the involved lung, providing an important clue to the presence of central airway obstruction and obviating pursuit of other considerations, such as pulmonary embolism.

Treatment of respiratory failure due to atelectasis is directed toward the combined goals of adequate oxygenation and re-expansion of lung segments. Supplemental oxygen should be titrated to achieve an arterial oxyhemoglobin saturation of at least 90%. Refractory hypoxemia, severe respiratory distress, progressive hypercapnia, or inability of the patient to clear copious airway secretions should prompt immediate intubation and mechanical ventilatory support. This lifesaving intervention permits more efficient delivery of oxygen, secures access for suctioning of the airways, and facilitates performance of bronchoscopy should it be necessary. Moreover, the positive pressure and large tidal volumes delivered by the ventilator are often effective in rapidly re-expanding collapsed lung segments. In less dire circumstances, noninvasive ventilation may be effective, although it does not provide a conduit for airway suctioning.

Fiberoptic bronchoscopy is commonly employed in the treatment of serious atelectasis, but evidence suggests that it may be no more effective than standard chest physiotherapy. In the only randomized study directly comparing these strategies, immediate fiberoptic bronchoscopy did not result in more rapid or complete resolution of acute lobar atelectasis when compared with a regimen of deep breathing, coughing, suctioning of the intubated patient, aerosolized bronchodilator treatments, chest percussion, and postural drainage.[49] Resolution of atelectasis was dictated not by the treatment modality employed, but by radiographic evidence of central airway patency. In this regard, both chest physiotherapy and bronchoscopy were highly effective in the absence of an air bronchogram. In contrast, the presence of an air bronchogram, which indicates that the atelectasis is not due to proximal airway obstruction, was associated with minimal response to either modality. Based on this, standard respiratory therapy techniques applied to either the spontaneously or mechanically ventilated patient should be considered the mainstay of treatment for lobar atelectasis. Fiberoptic bronchoscopy should be reserved for those situations where chest physiotherapy is contraindicated (e.g., chest trauma, immobilized patient), poorly tolerated, or unsuccessful, or in the setting of life-threatening hypoxemia.

A number of other measures are commonly employed in the treatment of atelectasis. Judicious use of analgesia is an essential adjunct, permitting the patient to breathe deeply, cough forcefully, and comfortably participate in chest physiotherapy maneuvers. Care must be taken to avoid excessive sedation, which will offset the beneficial effects of pain control. Mucolytics, such as N-acetyl cysteine and hypertonic saline, are commonly administered in an effort to promote clearance of tenacious secretions; however, their efficacy in this setting has not been well documented. Nasotracheal suctioning of the nonintubated patient with a weak and ineffective cough can transiently clear secretions but can be associated with considerable patient discomfort.

■ Pneumonia

Pneumonia represents a significant cause of postoperative respiratory compromise and can precipitate acute respiratory failure, as well as complicate respiratory failure in the patient who is ventilator dependent for other reasons. The overall frequency of postoperative pneumonia approximates 2% in contemporary series but varies significantly depending on a number of identified risk factors. The type of surgery heavily influences the risk; in particular, the risk is greatest following aortic, thoracic, hepatopancreatobiliary, intestinal, and neurosurgical procedures.[50,51] Patient-specific risk factors that have been identified include advanced age, current or recent smoking, COPD, and dependent preoperative functional status.[50,51] Two risk calculators, employing a number of these patient-related and procedure-related factors, have been developed; the more recent and comprehensive calculator is available at *www.surgicalriskcalculator.com/postoperative-pneumonia-risk-calculator*.[50,51] Neither calculator has been externally validated.

Several additional risk factors are not addressed in the risk calculators cited above. The presence of a nasogastric tube and the use of gastric acid suppressive medications, commonly employed interventions in postoperative patients, have been cited as risk factors for nosocomial pneumonia in general.[52] The need for postoperative mechanical ventilatory support is also an important risk factor, as mechanically ventilated patients in general have a 6- to 21-fold increased risk of pneumonia compared with nonventilated patients.[53]

Diagnosis of postoperative pneumonia is based upon the presence of conventional clinical features—fever, leukocytosis, purulent sputum, and radiographic infiltrates. Alternative etiologies of radiographic infiltrates that must be considered in the postsurgical patient include atelectasis, pulmonary edema, infarction or hemorrhage due to pulmonary emboli, pulmonary contusion, and chemical pneumonitis. Antibiotic selection should be guided by results of sputum cultures in the nonintubated patient. In mechanically ventilated patients, semiquantitative cultures of tracheal aspirates are recommended over bronchoscopic sampling of the distal airways using either a sterile sheathed brush or bronchoalveolar lavage combined with quantitative cultures.[54] Procalcitonin levels are not recommended in the diagnosis of nosocomial or ventilator-associated pneumonia due to highly variable performance characteristics.[54] Further complicating reliance on this biomarker in the postsurgical setting is the observation that major surgical procedures as well as cardiopulmonary bypass can lead to elevation in procalcitonin levels.[55,56] While awaiting culture results (or in the absence of adequate samples), broad-spectrum antibiotics that include coverage of methicillin-resistant *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and other gram-negative bacilli should be initiated. The choice of empiric antibiotics should be informed by knowledge of the particular hospital's distribution of pathogens and their susceptibility patterns, as multidrug-resistant organisms are commonly encountered in surgical units.

■ Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is defined by the constellation of hypoxemic respiratory failure, diffuse pulmonary infiltrates, and the absence of clinical evidence of elevated left atrial pressure (Chapter 141). The histologic hallmark of ARDS is diffuse alveolar damage, a widespread injury to the alveolar–capillary membrane that leads to increased capillary permeability and development of noncardiogenic pulmonary edema. ARDS represents the end result of a variety of insults that either involve the lung directly (e.g., aspiration of gastric contents) or trigger pulmonary inflammation as part of a systemic process (e.g., sepsis). Many of the risk factors associated with development of ARDS are commonly encountered in surgical patients. In decreasing order of risk, these include sepsis, massive blood transfusion, pulmonary contusion, aspiration of gastric contents, and multiple fractures.[57] Causes of ARDS of particular relevance to the surgical patient, and, in some cases, unique to this population, are described in greater detail below.

Aspiration of Gastric Contents

Aspiration of gastric contents can rapidly lead to widespread acute lung injury and is an important cause of ARDS in the surgical patient. It is the third leading cause of anesthesia-related deaths, accounting for 10% to 30% of fatal outcomes. Aspiration typically occurs when the mechanisms of glottic closure and cough, which normally protect the airway, are compromised. In the surgical patient, the period of maximal vulnerability for aspiration spans from the induction of general anesthesia to full return of consciousness postoperatively. A number of factors combine to enhance the risk of aspiration during this period. Most important is the blunting of consciousness that accompanies induction and administration of general anesthesia. Insufflation of air into the stomach during induction may cause gastric distention and promote vomiting. Vomiting may also be provoked by noxious stimulation of the posterior oropharynx during intubation or extubation. Reflux of gastric contents is facilitated by medication-induced relaxation of the lower esophageal sphincter, placement of the patient in a supine position, and manipulation of the bowel during abdominal procedures. At the completion of surgery, extubation is commonly performed at a time when the patient, while able to ventilate adequately, may not yet be capable of fully protecting the airway. Indeed, upper airway reflexes remain significantly impaired for up to 2 h after recovery from anesthesia, even at a time when mental alertness has returned. Moreover, translaryngeal intubation, even when brief, may cause residual glottic dysfunction for up to 8 h following removal of the tube. While the risk of aspiration diminishes beyond the immediate perioperative period, it remains a concern in the patient receiving narcotic analgesia, which may not only induce vomiting but also depress consciousness.

The risk of aspiration during the immediate perioperative period was delineated in a survey of more than 215,000 general anesthetic procedures performed at the Mayo Clinic.[58] Aspiration was defined as the presence of bilious or particulate matter in the airways or the development of a new infiltrate on the immediate postoperative chest radiograph. The overall incidence of aspiration was only 0.03%, but the incidence was nearly fourfold higher (0.11%) in the setting of emergency surgery. In addition to the use of general anesthesia, other predisposing factors were present in more than half of the patients who aspirated. These included gastrointestinal obstruction, swallowing dysfunction, altered sensorium, previous esophageal surgery, and a recent meal. The majority of events occurred during laryngoscopy (in preparation for insertion of the endotracheal tube) and during tracheal extubation. Of patients who aspirated, 20% required postoperative mechanical ventilation in excess of 6 h; 5% died as a direct result of this complication. The use of laryngeal mask airway devices does not appear to be associated with an increased risk of aspiration despite the fact that these devices do not isolate the larynx from the gastrointestinal tract.[59]

Acidic gastric contents introduced into the airways are rapidly disseminated throughout the bronchial tree and lung parenchyma, producing an almost instantaneous chemical burn. In addition, acid aspiration triggers a more delayed inflammatory response, with release of inflammatory cytokines and recruitment of neutrophils into the lung. The result is injury to the alveolar–capillary membrane, with flooding of the interstitium and airspaces by proteinaceous edema fluid. Surfactant levels drop precipitously due to both direct acid denaturation and diminished production, leading to alveolar instability and atelectasis. The magnitude of lung injury is directly related to the pH and volume of aspirated material. Initial studies in animals suggested that a pH of less than 2.5 and a volume in excess of 0.4 mL/kg are critical threshold values for the induction of lung injury.[60] While these values are now often quoted in the literature, their validity has been challenged by more recent studies demonstrating significant injury in association with lower volumes and higher pH. In particular, aspiration of bile is capable of inducing widespread injury even at a pH as high as 7.19. The presence of large food particles may further exacerbate the problem by causing airway obstruction and atelectasis. Notably, infection does not normally play a significant role in the initial lung injury from aspiration of acidic gastric contents, as the low pH serves to maintain relative sterility of the inoculum. However, gastric colonization with bacteria can occur in patients maintained on acid suppressive agents, those receiving enteral feeds, and those with gastroparesis or small bowel obstruction.

The diagnosis of aspiration is most firmly established in the setting of witnessed vomiting or recovery of gastric contents from the airways. More often, the diagnosis is suspected circumstantially in a patient with risk factors and a compatible clinicoradiographic picture. Massive aspiration presents with fever, tachypnea, and diffuse rales developing within several hours of the event. Wheezing is appreciated in approximately one-third of patients and may be due either to obstruction of airways by particulate matter or, more commonly, to reflex bronchospasm. Hypoxemia is universally present with massive aspiration and is sufficiently severe in the majority of patients to mandate use of mechanical ventilation. The initial presence of apnea or shock is particularly ominous and portends a high risk of subsequent death. Initial radiographic patterns vary, depending upon the volume, causticity, and distribution of the aspirated material. However, three general patterns have been described: (1) extensive bilateral consolidation resembling diffuse pulmonary edema; (2) widespread, but discrete, patchy infiltrates involving dependent areas of lung; and (3) focal consolidation usually localized to one or both lung bases.

The clinical course following massive aspiration is variable, but it typically diverges along one of several pathways. A minority of patients follow a fulminant course leading quickly to hypoxemic respiratory failure. More commonly, patients demonstrate progressive radiographic and clinical improvement over the first several days. Although most of these patients will go on to full recovery, a subset demonstrates secondary deterioration due to the development of nosocomial pneumonia. The overall mortality rate associated with massive aspiration is approximately 30% and exceeds 50% in those patients with initial shock or apnea, secondary pneumonia, or ARDS.

The treatment of respiratory failure secondary to aspiration is supportive and includes mechanical ventilatory strategies common to other forms of ARDS (Chapter 148). Bronchoscopy is indicated only when large airway obstruction by particulate matter is suspected on the basis of a localized wheeze or lobar atelectasis. Because acid is disseminated and endogenously neutralized within seconds, large-volume bronchoalveolar lavage is ineffective in attenuating the degree of injury and is not recommended. Studies of the administration of systemic corticosteroids in the treatment of aspiration pneumonitis have been inconclusive and do not currently justify their use. Similarly, use of prophylactic antibiotics is generally discouraged in the absence of supportive data and because of fear that this practice will preferentially select more highly resistant organisms. However, up to 40% of patients will develop a superimposed bacterial pneumonia within several days of the aspiration event, often heralded by a new fever, new or progressive infiltrates, and purulent sputum. Broad-spectrum antibiotic therapy is indicated at that time.

Postpneumonectomy Pulmonary Edema

Postpneumonectomy pulmonary edema describes the development of diffuse pulmonary edema in the remaining lung, in the absence of identifiable causes. While some authors apply this term exclusively in the setting of pneumonectomy, others have reported similar cases following lobectomy. Demonstration of normal pulmonary artery occlusion pressures and of protein-rich edema fluid in a small number of patients suggests that an increase in vascular permeability rather than hydrostatic pressure underlies the edema formation.[61] However, the exact mechanism responsible for lung injury remains a matter of conjecture. Mechanisms that have been advanced include hyperinflation and volutrauma resulting from single lung ventilation, endothelial injury due to hyperperfusion of the remaining lung, disruption of lymphatic drainage, and ischemia-reperfusion injury.[62]

The incidence of postpneumonectomy pulmonary edema ranges between 4% and 7%, in part reflecting variable definitions.[62] For unclear reasons, the complication is encountered more frequently following right pneumonectomy. The majority of cases develop by postoperative day 3. The observed mortality rate is in the range of 50% to 100%. Treatment is supportive, centering on lung-protective ventilator strategies. A nonrandomized trial suggested that the intraoperative administration of solumedrol was associated with a decreased incidence of postpneumonectomy pulmonary edema, but this is not considered standard of care.[63]

Cardiopulmonary Bypass

ARDS develops immediately following use of cardiopulmonary bypass (CPB) in approximately 1% of cases.[64] While factors unrelated to the use of CPB may be at play, there is evidence from both animal models and clinical studies to suggest that CPB activates a number of inflammatory pathways that could lead to acute lung injury. Activation of these pathways is thought to result in part from contact of neutrophils and platelets with the artificial surface of the bypass circuit. Additionally, during CPB, lung perfusion via the pulmonary circulation is interrupted, resulting in pulmonary parenchymal ischemia. When CPB is terminated, the resulting restoration of blood flow may produce an ischemia–reperfusion injury that triggers an inflammatory cascade.

The central role played by neutrophils in causing acute lung injury following CPB is supported by several lines of evidence: (1) bronchoalveolar lavage fluid from patients undergoing CPB contains an increased number of neutrophils; (2) plasma levels of neutrophil elastase and myeloperoxidase are increased; and (3) inhibition of neutrophil activation with pentoxifylline as well as neutrophil depletion attenuate the degree of pulmonary dysfunction.[64] Additionally, an increased expression of cell surface adhesion molecules has been demonstrated, which may promote neutrophil binding to pulmonary endothelium and release of proteolytic enzymes and reactive oxygen species. A number of other inflammatory mediators are released in association with CPB, including complement, proinflammatory cytokines, and prostaglandins.[64,65]

Demonstration of higher perioperative blood levels of interleukin 8 and neutrophil elastase when CABG is performed with CPB versus off-pump further supports the proinflammatory nature of CPB and helps to distinguish this from the effects of surgery itself.[66] Despite this, however, it is not clear that off-pump surgery mitigates the degree of perioperative pulmonary dysfunction. Perioperative oxygenation was higher in the off-pump cohort in one randomized trial,[67] but no difference was detected in another.[68]

Amiodarone

Amiodarone-induced pulmonary toxicity usually presents as a subacute illness characterized by cough, dyspnea, fever, and patchy pulmonary infiltrates. Rarely, the use of amiodarone has been linked to the development of ARDS immediately following cardiac and thoracic surgery. In most of the reported cases, amiodarone was administered preoperatively for varying periods of time for control of arrhythmias.[69] The majority of patients had no evidence prior to surgery of the more indolent form of amiodarone pulmonary toxicity. Development of ARDS also has been described in patients whose only exposure to amiodarone occurred in the postoperative period, when the drug was initiated as prophylaxis or treatment for atrial arrhythmias. In one report, postoperative ARDS developed in 11% of patients receiving amiodarone and in only 1.8% of untreated patients.[70] Notably, multiple retrospective cohort studies, prospective, randomized trials. and meta-analyses examining the use of prophylactic amiodarone in prevention of atrial fibrillation following thoracic and cardiac procedures did not detect an increased incidence of severe pulmonary complications in the treatment groups.[71–75] It has been postulated that the rarity of amiodarone-induced ARDS after the early reports in the 1990s may be due to lower cumulative doses of intravenous amiodarone and preferential use of oral administration subsequently employed in clinical practice.[76] Acknowledging the overall safety of the drug, professional society guidelines currently endorse the use of amiodarone in prevention of atrial fibrillation in high-risk thoracic and cardiac surgical patients.[76,77]

Specific perioperative factors that act in concert with amiodarone to produce acute lung injury remain to be defined. Some authors have suggested that exposure to high levels of supplemental oxygen may be a contributing factor. The diagnosis rests on exclusion of other causes rather than on specific diagnostic tests or histology. In addition to stopping the drug, high doses of corticosteroids are often given, but support for this is anecdotal at best.

Transfusion-related Acute Lung Injury

The transfusion of blood and blood products has been linked to the development of acute lung injury in two ways. An association between massive blood transfusion (>15 units/24 h) and ARDS has been noted in epidemiologic studies, but it remains unclear whether this link is truly causal or is indirect and reflective only of the critically ill nature of the patient requiring such massive transfusion support.[57] Acute lung injury can also be associated with the transfusion of a single unit of blood or blood components, an entity known as *transfusion-related acute lung injury (TRALI)*. TRALI is operationally defined as the acute development of hypoxemia and bilateral radiographic opacities during or within 6 h of a completed transfusion, in the absence of evidence of circulatory overload or alternative etiologies of acute lung injury.[78]

The mechanism underlying TRALI was initially determined to involve passive infusion via transfused blood products of donor-derived antibodies directed against recipient leukocytes. These antibodies are typically contained in blood products obtained from multiparous female donors, whose exposure to foreign human leukocyte antigen (HLA) or neutrophil antigens occurred during prior pregnancies. When transfused into a recipient with cognate antigens, these antibodies result in leukoagglutination and activation of recipient granulocytes or monocytes within the pulmonary microvasculature, triggering increased capillary permeability and the development of noncardiogenic pulmonary edema. For unclear reasons, anti–HLA class II antibodies appear to pose a greater risk than class I.[79] Less commonly, the leukoagglutinating process can be triggered by an interaction between recipient anti-HLA or antineutrophil antibodies and donor-derived leukocytes contained in the transfused blood products.[80]

While ample clinical and animal model evidence exists to support the antibody hypothesis,[78,81] several lines of evidence suggest that other factors also may be involved. First, not all patients who receive blood products containing recipient-specific anti-HLA or antineutrophil antibodies develop TRALI. Second, in a significant minority of cases, leukoagglutinating antibodies cannot be detected in either the donor or recipient. This has prompted the proposal of an alternative “two hit” mechanism, whereby an initial event is required to prime recipient neutrophils and a second event leads to activation of primed neutrophils.[78,81] Priming events that have been associated with an increased risk of TRALI include recent surgery, CPB, active infection, sepsis, and chronic alcohol abuse.[79,82,83] The second event involves transfusion of substances that trigger neutrophil activation: either antileukocyte antibodies or biologically active lipids resulting from breakdown of stored blood products.

Up to half of TRALI cases are detected in surgical patients in the immediate postoperative period, a fact that likely reflects the frequent need for transfusions in this setting and the close monitoring of cardiopulmonary function in the postanesthesia recovery area.[84–86] Cardiac surgery patients constitute the largest group, possibly due to the priming effect of CPB.[83,86] In one study of 668 patients undergoing cardiac surgery, TRALI was documented in 16 (2.4%).[83] Although virtually all blood products have been implicated, the risk of TRALI is highest in association with fresh frozen plasma and platelets.[80,81]

Clinically, TRALI is characterized by the abrupt onset of dyspnea and hypoxemia during or shortly following transfusion of blood products. Accompanying features include fever, chills, and hypotension. Respiratory distress and hypoxemia are of sufficient magnitude to require mechanical ventilatory support in up to 45% of cases.[80] The differential diagnosis includes volume overload, congestive heart failure, myocardial infarction, and aspiration. Although many cases are self-limited, with clearing of infiltrates and improved oxygenation over several days, mortality rates of 5% to 20% have been reported.[80,83]

When TRALI is suspected, the blood bank should be notified. Ideally, this should trigger testing of all donor specimens (typically retained by the blood bank) for the presence of anti-HLA and antineutrophil antibodies. However, the expense and time required often prevent blood banks from performing these studies.

Acute Exacerbations of Pulmonary Fibrosis

Patients with idiopathic pulmonary fibrosis (IPF) can experience sudden and dramatic respiratory decompensation in the absence of identifiable precipitants. Referred to as an exacerbation of IPF, this phenomenon is characterized by acutely worsening hypoxemia in association with new bilateral ground glass opacities or consolidation on chest CT not fully explained by cardiac failure or volume overload.[87] The histologic hallmark is diffuse alveolar damage, superimposed on underlying usual interstitial pneumonia.[88]

The immediate postoperative period following lung surgery is one of the settings in which acute exacerbations of IPF have been reported to occur.[89–91] Most cases have occurred following either lung resection for lung cancer or lung biopsy for diagnosis of IPF. The reported incidence ranges from 2% to 7%. The mechanism by which surgical manipulation of the lung could cause an exacerbation is currently speculative. Mortality associated with postoperative acute exacerbations is high, ranging from 50% to 100%. Steroids and other immunosuppressive agents are commonly initiated, but there is no compelling evidence for efficacy.[87,92,93] Lung transplantation may be an option in select cases.

■ Phrenic Nerve Injury and Diaphragmatic Dysfunction

Phrenic nerve injury is a well-described complication of CABG. In the past, this complication arose chiefly from the use of iced saline slush placed in the pericardium for topical cooling of the heart. Thermal injury causes both demyelination and axonal degeneration of the nerve, with slowing of conduction and impaired activation of the diaphragm. The use of topical cooling techniques has fallen out of favor largely because of this potential complication. However, the phrenic nerves can also be injured by traction, ischemia, use of diathermy, or transection during sternal retraction and harvesting of the internal mammary arteries. Unilateral phrenic nerve injury, typically involving the left phrenic, has been reported in approximately10% of patients undergoing CABG.[45,94] Bilateral phrenic nerve injury was reported to occur in 1% to 3% of cases in the era of widespread topical cardioplegia usage but is now a rare event. Phrenic nerve injury is not restricted to CABG but is also seen in association with other cardiac procedures, thoracic surgery, neck surgery, and liver transplantation.

Although typically inconsequential in the otherwise healthy patient, unilateral diaphragmatic paralysis can lead to significant respiratory compromise in patients with underlying chronic lung disease or those who are otherwise marginal. In patients with COPD, for example, the duration of postoperative mechanical ventilation and the rate of reintubation are higher for those with versus without unilateral phrenic nerve injury following CABG.[95] Bilateral diaphragmatic paralysis results in marked impairment in pulmonary function and frequently leads to respiratory failure. In the proper setting, phrenic nerve injury should be suspected when attempts to wean a postoperative patient from mechanical ventilation result in progressive hypercapnia or atelectasis. The spontaneously breathing patient will often complain of orthopnea, which may be misinterpreted by the unsuspecting clinician as indicative of congestive heart failure. However, orthopnea is actually due to further impairment in diaphragmatic function resulting from loss of gravitational assistance in the supine position. The detection of inspiratory thoracoabdominal paradox—an inward movement of the abdominal wall with simultaneous expansion of the thorax—is an important bedside clue to the presence of bilateral diaphragmatic paralysis and is best evoked in the supine position. The chest radiograph also may hold important clues, demonstrating either unilateral or bilateral elevation of the diaphragms and accompanying basilar atelectasis. However, these findings are not specific for phrenic nerve injury and may also be due to splinting or abdominal distention. A reduced maximum inspiratory pressure recorded at the mouth is another sensitive but nonspecific indication of significant diaphragmatic dysfunction.

Unilateral diaphragmatic paralysis can be readily diagnosed by fluoroscopic inspection, which reveals paradoxical upward movement of the affected hemidiaphragm with a maximal inspiratory effort (“sniff”). The situation is more problematic with bilateral diaphragmatic dysfunction. In this setting, patients often assume an altered breathing pattern marked by active contraction of the abdominal muscles during expiration, forcing the flaccid hemidiaphragms upward. With subsequent inspiration, the abdominal muscles relax and the hemidiaphragms descend briefly, potentially creating the false impression that they are functional. Because of this, fluoroscopy may not be confirmatory in these patients. Ultrasound has emerged as a simple bedside test for assessing diaphragmatic function. Thickening of the diaphragm with inspiration reflects diaphragmatic shortening, and failure to observe this sign is indicative of diaphragmatic paralysis. Ultrasound can thus be used to diagnose both unilateral and bilateral paralysis and can be performed serially to assess for recovery of function.[96]

The gold standard for confirmation of phrenic nerve injury is electrophysiologic testing, although even this methodology is occasionally flawed. The phrenic nerve is stimulated transcutaneously in the neck, and the diaphragmatic electromyogram (EMG) is recorded by surface electrodes placed in the seventh intercostal space at the costochondral junction. Demonstration of a prolonged latency between nerve stimulation and diaphragmatic action potential confirms a diagnosis of demyelinating injury. It is more difficult to interpret the significance of diminished amplitude or complete absence of the surface recording of the diaphragmatic EMG. This finding could represent either phrenic nerve injury/transection or failure to properly localize the diaphragm, which is typically shifted caudally in the postoperative patient and, therefore, away from the surface electrodes. Direct puncture of the diaphragm with a recording electrode may be employed to clarify this issue, but the technique requires a high level of expertise and carries a risk of pneumothorax.

Nontraumatic causes of phrenic nerve injury and diaphragmatic dysfunction can also lead to prolonged respiratory failure and delayed weaning in the surgical patient. Phrenic neuropathy can be a component of a more generalized polyneuropathy of critical illness, commonly encountered in the wake of an episode of severe sepsis or systemic inflammatory response syndrome. A critical illness myopathy affecting the diaphragms and other muscles of respiration can be encountered under the same circumstances. Finally, diaphragmatic dysfunction can arise as a component of a myopathy induced by the concurrent use of high-dose systemic corticosteroids and neuromuscular blocking agents.

Patients with diaphragmatic dysfunction are generally well suited for noninvasive positive pressure ventilatory support if they are awake and able to effectively handle respiratory secretions. Tracheostomy is indicated for patients with ineffective cough and those who cannot be weaned from conventional mechanical ventilation. The prognosis for patients with thermal or traction injury of the phrenic nerve is favorable; recovery is typically complete, but often protracted. In symptomatic patients with unilateral diaphragmatic paralysis due to transection of the phrenic nerve, surgical placation of the flaccid hemidiaphragm may lead to improved pulmonary function and successful liberation from mechanical ventilation.[97]

■ Pulmonary Embolism

An increased risk of pulmonary embolism (PE) accompanies a number of surgical procedures, including upper abdominal, neurosurgical, cardiac, major urologic, and lower extremity orthopedic procedures. Other, nonsurgical risk factors that predispose the patient to PE may also be present, including obesity, immobility, and underlying malignancy. Although alterations in gas exchange typify pulmonary embolism, frank hypoxemic respiratory failure is relatively uncommon and suggests massive clot burden. Lesser degrees of clot burden may produce equally devastating physiologic impairment in patients with underlying pulmonary disease.

While anticoagulation with heparin forms the mainstay of therapy for the otherwise stable patient, the presence of life-threatening hypoxemia and/or hemodynamic instability should prompt consideration of alternative or additional interventions. The use of systemic thrombolytic therapy in the postoperative period is limited by the risk of precipitating bleeding at the site of recent surgery. This risk appears to fall to an acceptable level beyond the seventh postoperative day; the exception is intracranial surgery, which contraindicates use of lytic agents for at least 2 months. Several catheter-directed options, including infusion of low-dose thrombolytics and suction embolectomy, as well as surgical embolectomy are alternative considerations in the deteriorating patient for whom systemic thrombolytics are either contraindicated or unsuccessful.[98]

■ Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) is highly prevalent within surgical populations, affecting approximately 25% of adults undergoing elective general surgical procedures,[99] greater than 30% of neurosurgical patients,[100] and greater than 70% of morbidly obese patients undergoing bariatric surgery.[101] It is characterized by repetitive upper airway obstruction during sleep, resulting in arterial desaturation, hypercapnia, and arrhythmias. The perioperative period is a particularly precarious time for patients with this disorder. Because of alterations in oropharyngeal anatomy that commonly accompany obesity and OSA, orotracheal intubation at the time of induction may be difficult. The use of anesthetics, opioids, and sedatives diminishes the activity of the upper airway dilator musculature and concurrently dampens respiratory arousal mechanisms that can terminate obstructive apneas. These effects lead to an increase in the frequency and duration of obstructive apneas that, in turn, can place the surgical patient at significant risk for serious respiratory complications. A meta-analysis of 13 studies involving almost 4000 patients demonstrated that the incidence of postoperative respiratory failure was significantly higher among patients with OSA compared to those without.[100] Analysis of a national database of approximately 6 million surgical patients similarly demonstrated that OSA increased the risk of postoperative intubation and mechanical ventilation fivefold after orthopedic procedures and twofold after general surgical procedures.[102]

As many as 80% of patients with OSA are undiagnosed at the time of surgery.[99] Identification of high-risk candidates with OSA prior to surgery is thus an essential strategy in minimizing the adverse impact of OSA on postoperative outcomes. Several easily administered screening tools have been developed and validated that can be incorporated into the preoperative assessment of surgical candidates. For example, the STOP-Bang tool uses a self-administered four-item questionnaire in conjunction with assessment of four patient characteristics (Table 103-5). It has positive predictive and negative predictive values of 52% and 90%, respectively,

TABLE 103-5 STOP-Bang Scoring Model for Preoperative Assessment of OSA Risk

Snoring: Do you snore loudly?
Tired: Do you often feel tired, fatigued, or sleepy during daytime?
Observed: Has anyone observed you stop breathing during your sleep?
Blood **P**ressure: Do you have or are you being treated for high blood pressure?
BMI: BMI more than 35?
Age: Age over 50 years?
Neck Circumference: Neck circumference greater than 40 cm?
Gender: Male?

High risk of OSA: answering yes to three or more items. Low risk of OSA: answering yes to less than three items.

Modified with permission from Chung F, Elsaid H. Screening for obstructive sleep apnea before surgery: why is it important? Curr Opin Anaesthesiol. 2009;22(3):405–411.

in identifying surgical candidates with moderate to severe OSA (apnea–hypopnea index >15).[103]

A number of measures can be employed in an attempt to reduce the risk of serious pulmonary complications in surgical patients with OSA.[101] The anesthesiologist should be made aware of the potential for a difficult intubation, and emergency airway devices should be readily available. Ideally, shorter-acting anesthetic agents should be employed. Intraoperative use of opioids should be minimized; if deemed necessary, use of ultra-short-acting agents such as remifentanil is preferable. Extubation following completion of surgery should be carried out only after the patient is fully awake and residual effects of intraoperative neuromuscular blockade have fully dissipated. Application of continuous positive airway pressure (CPAP) immediately after extubation should be considered, particularly if apneic episodes are noted in the recovery area. Non-opioid analgesics should be used in an attempt to avoid or minimize use of opioids in the postoperative period.

USE OF NONINVASIVE POSITIVE PRESSURE VENTILATION AND HIGH-FLOW NASAL OXYGEN IN THE POSTOPERATIVE SETTING

For patients with respiratory failure refractory to conservative measures, endotracheal intubation is the standard means to facilitate mechanical ventilatory support. However, endotracheal intubation is associated with a number of untoward effects including airway trauma, increased risk of nosocomial pneumonia and sinusitis, and the frequent need for heavy sedation that, while addressing patient discomfort, often prolongs the process of weaning and extubation. The desire to avoid endotracheal intubation has led to the use of noninvasive positive-pressure ventilation (NIPPV), employing a tight-fitting nasal or full face mask as the interface between patient and ventilator. NIPPV has been demonstrated to reduce the risk of intubation among patients with postoperative hypoxemic respiratory failure following lung resection surgery[104] and abdominal surgery.[105] It has also been shown to reduce the risk of reintubation when used preemptively following extubation in various surgical populations.[106,107] While there has been a concern about using NIPPV following esophageal or gastric surgery, experience suggests that this can be accomplished safely.[108] In this setting, care must be taken to avoid gastric distention, using a nasogastric tube for decompression if necessary, and the magnitude of positive-pressure ventilation employed should be limited to <20 cm H_2O. Since NIPPV often requires a period of acclimation, it should not be used in unstable patients. Other contraindications to its use include depressed or agitated mental status, inability to protect the airway, and compromised airway clearance due to copious secretions or weak cough.

More recently, high-flow nasal oxygen has emerged as an alternative means of supporting patients with hypoxemic respiratory failure. A large clinical trial involving 830 cardiothoracic surgical patients who had developed acute respiratory failure or were deemed to be at risk for respiratory failure following extubation randomized patients to receive either high-flow nasal oxygen or BiPAP.[109] Rates of treatment failure (intubation, switch to the alternative treatment arm, or study-treatment discontinuation) were equivalent for the two groups, supporting the use of high-flow nasal oxygen in the postoperative setting in this particular patient population. Prophylactic use of high-flow nasal oxygen immediately after extubation was also found to decrease the risk of reintubation and escalation of respiratory support compared with conventional oxygen therapy following cardiothoracic surgery[110] but not following abdominal surgery.[111]

CHAPTER 104

Thoracic Trauma

Seth A. Bellister
Bradley M. Dennis

INTRODUCTION

Injury to the chest and its contents occurs in nearly a quarter of all trauma patients.[1] Thoracic trauma constitutes a diverse spectrum of disease that can be rapidly progressive and that can have both immediate life-threatening consequences and the potential for long-term sequelae. This chapter addresses management of specific injuries to the thoracic contents and chest wall, many of which require intervention immediately or within the first few hours of hospitalization.

Anatomy

Due to the size of the chest, it is susceptible to injuries from both blunt and penetrating mechanisms. While lethal injuries can occur anywhere within the chest, the most concerning site of injury is classically described as "the box." The box is an area circumscribed by vertical lines drawn down from the mid-clavicle at the level of the sternal notch to the costal margin and then across. This external landmark overlies the cardiac silhouette and the great vessels of the thorax including the pulmonary hila bilaterally. However, this anatomic view oversimplifies the problem. The box must be considered as a three-dimensional structure wherein injuries to the posterior and lateral thorax can jeopardize vital structures.

It is important to emphasize that injuries outside the box also can be life threatening, both acutely and in a more chronic setting. Most specifically, tension pneumothorax can present acutely after injury well outside the box. It must not be ignored that injuries to the bony skeleton of the chest may be acutely life threatening but also may lead to long-term sequelae that compromises quality of life.

Initial Evaluation

The initial workup of all trauma patients proceeds in an organized algorithmic fashion in order to maximize early identification of life-threatening injuries and prioritize their management while minimizing missed injuries of less morbid consequence. At the time of presentation, injuries to the thorax often cause a significant amount of stress to the prehospital provider and emergency department staff. It is incumbent that providers do not develop tunnel vision and lose sight of the basic strategies of trauma management. In patients presenting with cardiovascular compromise, early definitive management of the airway should be undertaken regardless of suspected injuries. In the acute setting, with minimal history, airway management should occur with standard rapid sequence intubation practices.

Once the airway has been secured, prompt evaluation of breath sounds may simultaneously confirm proper placement of the endotracheal tube, as well as indicate life-threatening causes of cardiovascular collapse. Chest x-ray (CXR) may be ordered at this time but not performed until breath sounds have been evaluated, intravenous access secured, and resuscitation initiated. Interventions on the airway, breathing, and circulation should preclude all imaging.

Pleural Complications

Two imminently life-threatening pleural complications that require immediate intervention are tension pneumothorax and massive hemothorax. Non-life-threatening pneumothoraces and hemothoraces also are commonly encountered in the trauma patient and often require intervention, albeit less urgently.

Tension Pneumothorax

Absent breath sounds in a traumatically injured patient with hemodynamic instability should prompt immediate suspicion of tension pneumothorax. Other symptoms and signs of tension pneumothorax include chest pain, air hunger, tracheal deviation away from the side of injury, tachypnea, jugular venous distention, and hemodynamic instability. Hemodynamic instability typically manifests with tachycardia and hypotension due to decreased venous return secondary to the increase in intrathoracic pressure created by the pneumothorax. Diagnosis of tension pneumothorax should be made based on clinical findings rather than waiting for confirmation with radiographic studies.

Tension pneumothorax requires immediate and definitive treatment. Needle thoracostomy may be considered strictly as a temporizing measure and involves the use of a 14-gauge needle 5 inches in length inserted into the second intercostal space at the midclavicular line.[2] The needle may also be placed in the anterior axillary line in the fourth or fifth intercostal space. Needle thoracostomy is associated with a failure rate as high as 40%, most frequently due to failure to access the pleural cavity.[3] This has led many to question the usefulness of needle thoracostomy.[4] Failure of needle thoracostomy is more common in women than men, and the likelihood of a failed procedure may be increased by poor patient positioning.

Definitive management of tension pneumothorax is best achieved with a tube thoracostomy. Tube thoracostomy can be performed through an open surgical approach or percutaneously. The increased use of point-of-care ultrasound has allowed for the successful and reproducible identification of pneumothorax and has facilitated the safe and accurate performance of bedside tube thoracostomy. Several systems are available for percutaneous thoracostomy. The most common system is the Wayne catheter. The Wayne catheter uses standard Seldinger technique with step-up dilation to allow easy placement of a 14F pigtail catheter. Upon placement of the chest tube, a return of hemodynamic stability and breath sounds to the affected hemithorax confirm that the tension pneumothorax has been adequately addressed. Note should be made of the magnitude of any ongoing air leak and any associated bleeding.

Simple Pneumothorax

Not all pneumothoraces require emergent intervention. Simple pneumothorax presents in a hemodynamically stable patient with ipsilateral chest pain and/or shortness of breath. Some patients will have accompanying hypoxia and tachypnea. However, there is a population of patients that will present asymptomatically. Most simple pneumothoraces can be identified on chest x-ray. However, in 15% to 20% of cases, pneumothorax is not apparent on chest x-ray and only seen on CT scan.[5–7] Often, simple pneumothoraces can be managed without intervention. Indeed, regardless of blunt or penetrating mechanism, one study suggested that most pneumothoraces measuring less than 35 mm on CT scan (the radial distance between the parietal and visceral pleura in a line perpendicular to the chest wall on axial imaging) can be safely observed.[8]

Hemothorax

Large-volume blood loss into the pleural space is typically classified as more than 1.5 L immediately draining into the chest tube reservoir after tube thoracostomy. This should prompt immediate surgical exploration.[9] Additionally, the tube output should be monitored at the bedside and more than 200 mL/h over the course of 4 h should prompt surgical re-evaluation. However, the decision to operate should be based on the overall clinical picture, presumed injury, and velocity of blood loss rather than a strict output number. Indeed, regardless of output, a hemodynamically unstable patient need not wait four hours for repair to meet an arbitrary volume target.

While management of massive hemothorax is frequently surgical, smaller hemothoraces may often be managed without any intervention. Hemothorax often results from lacerated muscle and intercostal vessels after rib fractures. Small collections will often be reabsorbed. However, larger collections may organize or become infected.[10] The decision to evacuate a hemothorax should be based on clinician judgement.[11] Symptomatic hemothorax and larger collections are more likely to require drainage than small, asymptomatic ones. Thoracostomy tube drainage is the mainstay of treatment. Historically, large-bore tubes (36F and 40F) were recommended. More recent data suggest that smaller tubes are just as effective, even tubes as small as 14F.[12,13] The primary goal with any thoracostomy tube is complete hemothorax drainage. Larger retained collections (>200 mL) carry a higher risk of subsequent complications than small collections. In fact, up to 26% of patients with retained hemothoraces will develop an empyema.[14] In order to minimize complications related to retained hemothorax a defined, institution-specific algorithm should be created. By using a stepwise algorithm, the number of patients requiring operative management of retained hemothorax can be reduced.[15] Early intervention (day <7) with video-assisted thoracic surgery (VATS) can prevent development of empyema or fibrothorax with resultant entrapment of the lung. There is an evolving role for the instillation of thrombolytics via image-guided chest tubes.[16–18] However, ideal dosing, timing, and duration remain active areas of study. Randomized controlled trials comparing thrombolytic therapy to surgical treatment of retained hemothorax have not been performed. A retrospective series of 65 patients with posttraumatic retained hemothorax demonstrated that VATS led to decreased length of stay and need for subsequent thoracotomy compared to initial management with intrapleural instillation of streptokinase.[19] Based on available evidence, trauma surgery practice guidelines currently recommend VATS as first-line treatment for retained hemothorax over thrombolytics or additional thoracostomy tubes.[11,20,21] Several protocols are published; however, one has not been shown to be clearly superior to any other. Despite current approaches, as many as one in five patients will ultimately require open thoracotomy for management of retained hemothorax or subsequent empyema.[22]

Chest Tube Management

Much emphasis has traditionally been placed on chest tube position. Traditional teaching was that pneumothorax should be treated with an anteriorly placed chest tube and hemothorax should be treated with a posteriorly placed tube. There is less emphasis on tube position in contemporary management in favor of tube efficacy.[24,25] If the lung re-expands then the tube has been adequately placed and does not require further intervention or manipulation. If, however, the lung does not re-expand a second tube should be placed. Operative intervention must also be considered in the setting of failure of the lung to re-expand with an adequately placed tube. This may be due to a large lung laceration or injury to the bronchial tree. Alternatively, a chest full of clotted blood may prevent lung re-expansion, regardless of tube size or number.

■ Pneumomediastinum

Another form of barotrauma resulting from blunt trauma is pneumomediastinum, often associated with subcutaneous emphysema. This finding is seen in up to 10% of patients with severe blunt chest trauma. It is most commonly the result of the Macklin effect, a process initiated by alveolar rupture due to sudden increase in intrathoracic pressure, followed by dissection of extra-alveolar air along the bronchovascular sheaths into the mediastinum.[26] Pneumomediastinum resulting from this mechanism requires no intervention unless accompanied by pneumothorax. However, pneumomediastinum can also result from tracheobronchial or esophageal rupture—and for this reason, its presence should prompt performance of bronchoscopy and esophagoscopy or barium esophagram.

■ Pulmonary Contusion

Pulmonary contusions are often associated with chest wall injuries. These areas of contusion lose their functional capacity for gas exchange during respiration. In the setting of blunt chest injury, the effect of these injuries can be progressive and is often not apparent on initial chest x-ray. Like all contusions, this injury expands over the course of days and may ultimately compromise an initially stable patient. Treatment is largely supportive and should focus on limited utilization of crystalloid and avoiding overresuscitation to minimize the evolution of the contusion. As with supportive care of rib fractures, aggressive respiratory care including incentive spirometry, secretion clearance, and ambulation should be instituted as early as possible. When pulmonary contusions involve more than 20% of the total lung volume on CT imaging, the clinician should be mindful of impending respiratory compromise, as up to 80% of these patients will develop acute respiratory distress syndrome (ARDS) during the course of their hospitalization.[27] The need for mechanical ventilation should be determined based on usual clinical algorithms. Prophylactic intubation should not be considered in a patient with an uncompromised respiratory state. The decision to intubate often requires consideration of the number of associated rib fractures, age, and overall injury severity score rather than a single variable such as presence or absence of pulmonary contusion.

■ Tracheobronchial Injury

One rare cause of sudden cardiopulmonary compromise in both blunt and penetrating trauma is injury to the tracheobronchial tree. These injuries most commonly follow a penetrating mechanism but may be the sequelae of high speed-rapid deceleration injury. Not surprisingly, penetrating injuries occur most commonly at exposed points such as the cricoid cartilage, while blunt injuries occur most commonly within 2 cm of the carina, a relatively fixed point of the respiratory tree. Diagnosis is considered based on the presence of air in non-anatomic places such as subcutaneous tissue and mediastinum. Crepitus noted on examination of the neck should prompt investigation of a penetrating tracheal injury. Findings of blunt injury may be more subtle and include dyspnea, respiratory distress, dysphonia, hemoptysis, continuous air leak from a chest tube, and persistent pneumothorax despite adequately placed chest tube.

Tracheal injury should not preclude an attempt at endotracheal intubation, if clinically indicated, but this should be approached with caution. Emergent intubation should be reserved for patients who are in respiratory distress, for cases of impending respiratory failure, and for patients who demonstrate signs of airway compromise. For more stable patients, emergent intubation should not be performed simply because a tracheal injury has been identified. A more thoughtful and measured approach is required for this patient cohort. The location of this procedure (i.e., operating room vs. emergency department) should be chosen based on proceduralist expertise, institutional resources, and availability of resources. Intubation should be performed by a proceduralist with significant experience in difficult airway management. Surgical backup should be present for the intubation in the event that a surgical airway is needed. Fiberoptic intubation or bronchoscopic guidance may be required for more proximal injuries to ensure the endotracheal tube cuff extends below the area of injury. A prompt surgical evaluation by a trauma surgeon and/or otolaryngologist as early as possible is essential in this setting to ensure proper airway management, clinical assessment, and surgical repair.

Cardiac Tamponade

Another cause of sudden hemodynamic instability in the setting of chest trauma is cardiac tamponade. An injury within "the box" is the most common predisposing factor. While diagnostic criteria such as Beck's triad—the constellation of hypotension, muffled heart sounds, and distended neck veins—may be present to varying degrees, cardiac tamponade is often diagnosed on resuscitative thoracotomy where a simple pericardiotomy offers diagnostic and therapeutic effect. If the patient survives the primary survey, workup of pericardial effusion can be completed using point-of-care ultrasound, known as a "focused abdominal sonogram for trauma" or FAST examination (Fig. 104-1). In the setting of trauma, identifying fluid contained in the pericardium regardless of tamponade physiology should prompt rapid surgical evaluation. The approach to this problem should be a subxiphoid pericardial window. If blood is identified in the effusion, the patient should undergo an emergent median sternotomy to adequately expose the heart and offer the best approach to any injuries that are identified. In more austere settings where surgical intervention is not an option, the use of ultrasound guidance to perform pericardiocentesis remains a temporizing option. It should be clear that this is not a definitive option, but rather, a maneuver to temporarily relieve tamponade pending definitive management.[28]

Blunt Cardiac Injury

Penetrating injuries can readily reveal themselves, although small injuries may be misjudged in their severity. Blunt cardiac injuries (BCIs), on the contrary, are often subtle and at times suggested only by the new onset of an arrhythmia or conduction abnormality in the setting of blunt chest trauma. The most common form of blunt cardiac injury is myocardial contusion. Because there is no consensus on diagnostic criteria for myocardial contusion, incidence figures following chest trauma vary widely in the literature. Because of its anterior location, the right ventricle is most susceptible to injury but left ventricular regional wall motion abnormalities also have been described. In keeping with the high frequency of right ventricular involvement, the most common ECG abnormality observed in the setting of myocardial contusion is new-onset right bundle branch block.[29] Other abnormalities include ST segment depression, varying degrees of heart block, nonsustained ventricular tachycardia, and atrial arrhythmias.[30] Neither sinus tachycardia nor bradycardia is considered an indicator of myocardial contusion. In cases of severe contusion, heart failure and cardiogenic shock can ensue.

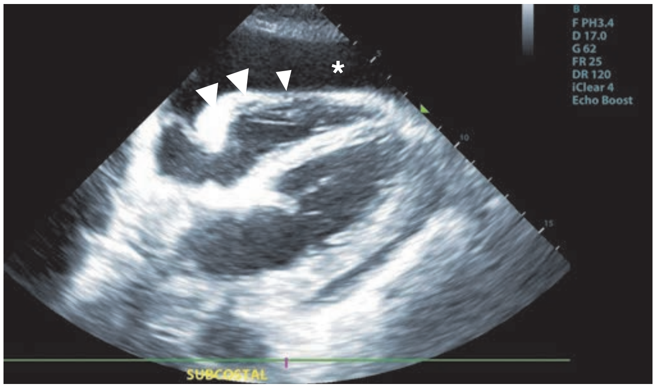

Figure 104-1 Ultrasound image showing pericardial fluid (*) and collapse of right atrium and ventricle *(white arrowheads)* consistent with cardiac tamponade. *(Reproduced with permission from Jeremy Boyd, MD.)*

Evaluation of suspected myocardial contusion from blunt cardiac injury is summarized in Fig. 104-2. Abnormalities detected on ECG often provide the first clue to the presence of myocardial contusion. If the ECG is abnormal, the next step in workup should be evaluation of cardiac enzymes. Creatine kinase has been studied extensively and found to be unreliable.[31] In contrast, troponin is specific to cardiac injury even in the setting of multisystem trauma.[32] Notably, a normal ECG is insufficient to rule out blunt cardiac injury, but the combination of a normal ECG *and* normal troponin has 100% negative predictive value for clinically significant blunt cardiac injury.[33] Persistent conduction abnormalities, high-grade arrhythmias, or hemodynamic instability should prompt further investigation with transthoracic echocardiography. In cases where significant chest wall injury, soft tissue damage, or dressings preclude transthoracic imaging, transesophageal echocardiography is advised.

The majority of blunt cardiac injuries are mild and self-resolving. Aggressive supportive care of hemodynamically significant cardiac injuries should be provided in an ICU setting. While most BCIs are nonsurgical, up to 20% of patients with BCI will require some intervention whether medical or surgical.[34]

Aortic Injury

Blunt injury to the thoracic aorta most commonly occurs at the anatomic tether points of the aorta: the root, the ligamentum arteriosum, and the diaphragm. Patients with complete transection of the aorta will likely not present to the emergency center with vital signs. However, hemodynamic stability does not preclude aortic injury.[35] Clinical suspicion for aortic injury should be elevated in patients sustaining high-velocity acceleration–deceleration injuries, for example, motor vehicle crashes, fall from height. The initial chest x-ray may suggest widening of the mediastinum. Other chest x-ray findings that may suggest thoracic aortic injury include rightward tracheal deviation, apical capping, loss of aortic knob, flattening of the left mainstem bronchus, loss of aortopulmonary window, and left hemothorax. However, these injuries are most readily diagnosed on a well-timed contrast-enhanced CT scan of the chest during the initial trauma evaluation (Fig. 104-3). This allows identification and grading of the injury.[36]

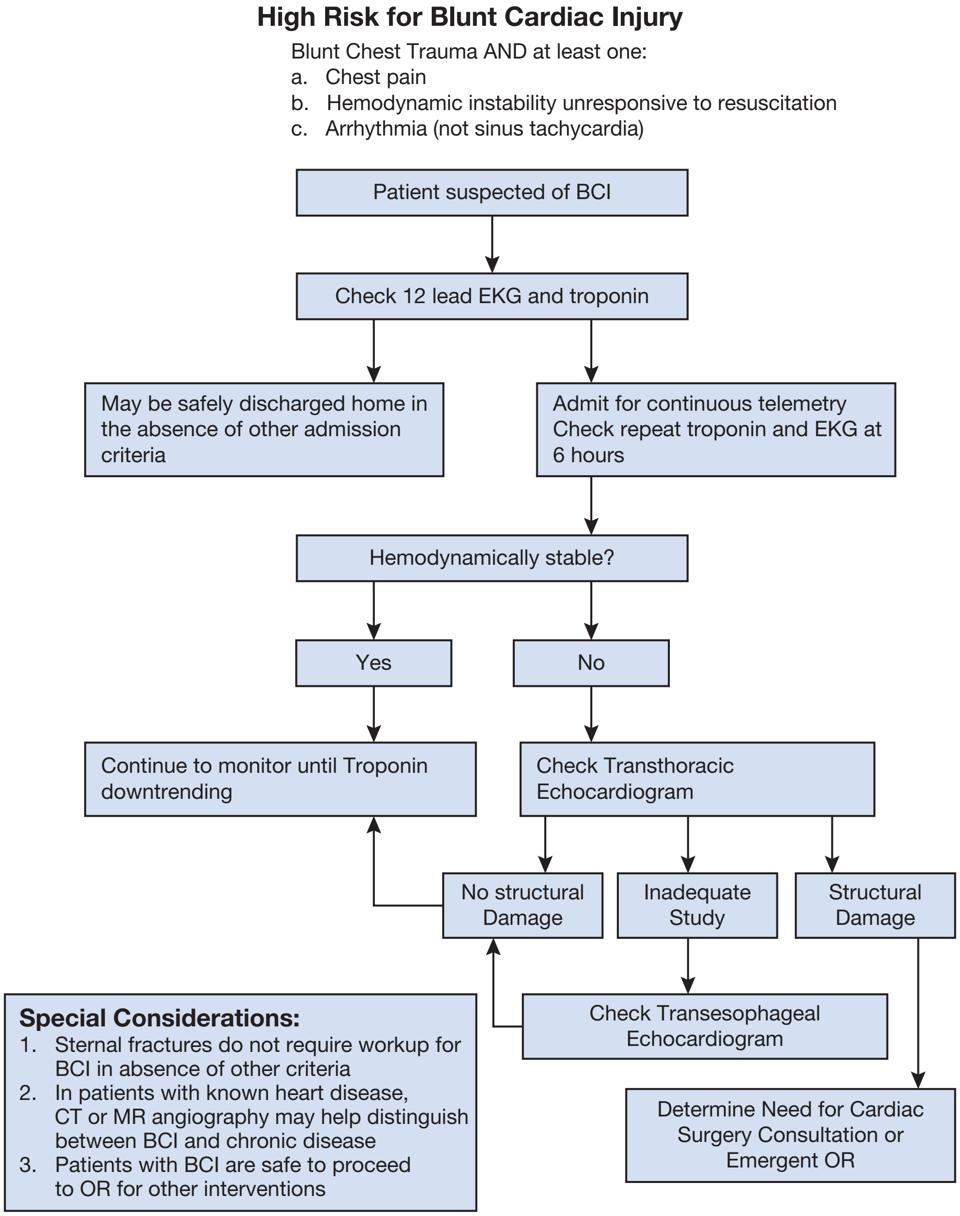
Moderate to high-grade aortic injuries almost invariably require some form of surgical intervention. The most common complications of aortic surgery are death, paraplegia, and renal failure. While renal failure rates are unaffected by the timing of repair, mortality and paraplegia rates are decreased when repair of the aorta is delayed >24 h.[37] Historically, aortic injuries were repaired in an open fashion using the "clamp and sew" technique. This technique was dependent largely on the individual surgeon's speed for good outcomes. More recently however, endovascular techniques have supplanted open surgery in the management of blunt aortic injuries.[38] These repairs require institutional and individual expertise and resources.

Skeletal Injuries of the Thorax

Below we briefly consider two common skeletal thoracic injuries: fractures of the sternum and ribs.

Sternal Fracture

Fracture of the sternum is most commonly identified on CT scan of the chest during the initial evaluation. This injury may be associated with a hematoma in the mediastinum. However, this is rarely of any significance. It was initially thought that sternal fractures may have some association with injury to the underlying heart, but more recent studies suggest that this concern is unfounded in the absence



High Risk for Blunt Cardiac Injury
Blunt Chest Trauma AND at least one:
a. Chest pain
b. Hemodynamic instability unresponsive to resuscitation
c. Arrhythmia (not sinus tachycardia)
Patient suspected of BCI
Check 12 lead EKG and troponin
May be safely discharged home in the absence of other admission criteria
Admit for continuous telemetry Check repeat troponin and EKG at 6 hours
Hemodynamically stable?
Yes
No
Continue to monitor until Troponin downtrending
Check Transthoracic Echocardiogram
No structural Damage
Inadequate Study
Structural Damage
Check Transesophageal Echocardiogram
Determine Need for Cardiac Surgery Consultation or Emergent OR
Special Considerations:
1. Sternal fractures do not require workup for BCI in absence of other criteria
2. In patients with known heart disease, CT or MR angiography may help distinguish between BCI and chronic disease
3. Patients with BCI are safe to proceed to OR for other interventions

Figure 104-2 Workup for blunt cardiac injury.

of other evidence of cardiac injury (i.e., presence of ECG changes or troponin elevations).[39]

Rib Fractures

Chest wall injury is one of the most common injury patterns in trauma, present in 10% or more of all trauma admissions. It is also a significant marker of mortality, injury severity, and associated injuries. This is particularly true in elderly trauma patients (≥65 years), for whom rib fractures were associated with increased ventilator days, pneumonia rates, ARDS, and mortality compared to younger cohorts with similar injury patterns.[40]

Initial evaluation for chest wall injury should include a chest x-ray and possibly a CT scan of the chest. It is important to note that a plain chest x-ray will miss up to 75% of rib fractures.[41] Imaging should be used to quantify the number of ribs broken, the amount of displacement, and the location of each fracture. Additionally, the volume that can be generated on a bedside incentive spirometer should be recorded during the initial evaluation.[42] Physical exam should identify any point tenderness, as well as paradoxical motion that may represent a flail segment.

Flail chest represents a particularly morbid consequence of rib fractures. It is a clinical diagnosis most commonly defined as three consecutive ribs broken in two or more places such that this segment of the chest wall moves independently of the rest of the chest. Not all patients with the fracture pattern will have a clinically significant flail segment. It is an important distinction because 80% of patients with a flail chest will be admitted to the ICU and nearly 60% will require mechanical ventilation.[43] Identification of this injury is important, as the energy required to create a flail segment will often result in laceration and contusion of the underlying lung. This underlying lung injury creates ventilation–perfusion mismatches, a major contributor to respiratory failure in patients with flail chest. Additionally, the independent motion of the flail segment relative to the rest of the chest wall prevents maximal chest wall excursion and recoil and results in less intrathoracic pressure change (Fig. 104-4). The end result is decreased oxygenation and ventilation of the lung on the injured side. These two sequelae of flail chest in combination with the pain of multiple fractured ribs result in the high rates of respiratory failure requiring mechanical ventilation.

TABLE 104-1 Nonsurgical Pain Control Options for Patients with Multiple Rib Fractures

	Multimodal Pain Control	Thoracic Epidural Catheter	Erector Spinae Block	Paraspinal Block
Bilateral rib fractures	Yes	Yes	No	No
Fractures above T4	Yes	No	Yes	Yes
>6 rib fractures	Yes	Yes	Yes	No
Anticoagulated	Yes	No	Yes	Yes
Unable to tolerate PO	No	Yes	Yes	Yes
Recent or anticipated T-spine surgery	Yes	No	Yes	No
Invasive	No	Yes	Yes	Yes
Associated hypotension	No	Yes	No	No

In addition to ensuring adequate oxygenation and ventilation, the initial approach to management of rib fractures focuses on pain control. There are three possible components of pain control in the setting of chest wall injury: nonregional analgesia, regional/invasive anesthesia, and rib fracture stabilization. Table 104-1 shows the various nonsurgical analgesic options for patients with rib fractures and the settings in which each may be preferred or discouraged. Pain control should focus on nonsedating, nonnarcotic pain control in the initial phase. A combination of NSAIDs, acetaminophen, gabapentinoids, and muscle relaxers, as well as topical agents, should be initiated early based on institutional expertise.[44,45] The goal of this multimodal pain regimen is twofold. First, it should provide a reduction in clinical pain scores that consequently facilitate compliance with physical and respiratory therapy exercises. Second, it should limit the overall opiate requirement during a hospitalization. Should analgesia be inadequate with this initial regimen, pain control should escalate in a standardized fashion. Some protocols may institute enteral opiates, which are preferred to intravenous administration. Should IV opiates be required, patient-controlled analgesia (PCA) is the preferred delivery modality. In some institutions, an acute pain service may be called in to monitor pain in the setting of failed nonopiate pain regimens. In situations where opiate analgesia proves inadequate, continuous infusions of ketamine (0.1–0.25 mg/kg/h) and/or lidocaine (0.2 μg/kg/h) may provide improved pain relief. These medications need to be administered in a monitored setting.[46]

Regional anesthesia, including thoracic epidural anesthesia, intercostal nerve blocks, and paravertebral and erector spinae blocks, is a second modality that can be utilized for pain control. Regional anesthesia should be reserved for patients with more severe injuries or patients whose pain is inadequately managed with standard enteral pain control. The data on epidural pain control are highly variable.[47–54] Some centers have reported excellent results while others have not been able to identify a benefit. Epidural catheters are complicated by urinary retention, hypotension, and, rarely, epidural hematomas. Care should be exercised in patients with thrombocytopenia, cirrhosis, or anticoagulation or antiplatelet therapy. Because of the variability of the data, epidural catheters are only conditionally recommended by the Eastern Association for the Surgery of Trauma.[52]

Another regional anesthetic option is intercostal nerve blocks. This technique is commonly performed by manual palpation of the individual fractured ribs, which can be problematic for the patient. Once the fractured ribs are identified, anesthetic can be infiltrated from the level above the injured rib to the level below. This procedure carries a small risk of pneumothorax, which increases with each fractured rib as each intercostal neurovascular bundle must be injected individually. Additionally, identification of bony landmarks is difficult above the seventh rib because of overlying scapulae.[55]

A third option for regional anesthesia that may provide comparable efficacy to epidural anesthesia is paravertebral block.[49] This avoids the problem of manipulating the ribs as required for intercostal blocks while achieving the dermatomal coverage similar to epidural anesthesia. Paravertebral blocks are particularly useful for unilateral fractures, as the blocks are placed in a paravertebral location where the nerve roots exit the vertebral column.

The final strategy for pain control in the setting of rib fractures is surgical stabilization of the fractured ribs. While still controversial among trauma surgeons, there is a growing body of evidence that supports decreased opiate use in patients with early stabilization of rib fractures.[54–57] In addition, there is evidence that patients may avoid intubation and have fewer ICU days with early stabilization. As with many surgical therapies, institutional experience may be the most critical factor in establishing a successful rib fixation program.[57]

In addition to pain control, the role of respiratory therapy and nursing cannot be understated in the management of rib fractures. Pneumonia and respiratory failure are the most common complications of poor pulmonary hygiene. Respiratory therapy interventions include incentive spirometry and positive expiratory pressure devices to facilitate lung expansion, and airway clearance measures. Protocols that include early ambulation, bronchodilators, and nebulizers should be developed in order to minimize respiratory decline and maximize patient success.[58–60] Multidisciplinary pathways for respiratory care may contribute to decreased length of ICU stay and hospital length of stay.[61] In addition, these pathways have been shown to decrease pneumonia rates and overall mortality.[61]

CHAPTER 105

Developmental Disorders of the Lung

Himanshu Deshwal
Subha Ghosh

INTRODUCTION

The development of the lung starts at 4 weeks of gestation and continues through young adulthood. Any developmental abnormality during the growth of the lung may lead to anatomic and physiologic abnormalities, which in turn may lead to significant symptoms and a reduction in quality of life. Prenatal ultrasonography and Doppler technology as screening tools for fetal growth have led to early identification of most developmental anomalies, including pulmonary vascular abnormalities, and revolutionized pre-emptive management of these disorders.[1,2] Nonetheless, some developmental disorders of the lung may remain subclinical and escape diagnosis until adulthood.

Research using animal models and in vitro models has led to the identification of several genetic factors and signaling molecules that play a significant role in lung growth and morphogenesis.[3] Some lung abnormalities are part of genetic syndromes involving multiple organs that share the same molecular pathways of embryogenesis. While some lung abnormalities resolve spontaneously before birth, others persist, with a spectrum of severity ranging from asymptomatic to severe postnatal respiratory distress. Asymptomatic abnormalities often go undetected until adulthood when they are incidentally discovered on chest imaging and often misidentified as malignant or infectious lesions. Thus, an understanding of developmental defects of the respiratory system, with a clinicoradiologic approach, is critical for accurate identification and management of these patients. For ease of understanding, the developmental disorders of the lung can be classified as airway disorders, parenchymal disorders, and vascular disorders (Fig. 105-1).

DEVELOPMENT OF THE LUNG

Important considerations in lung development include stages of lung development, the role of fetal lung fluid in lung development, and associated molecular mechanisms.

Developmental Stages

Lung development starts at 4 weeks of gestation and is divided into five developmental stages known as the embryonic stage, pseudoglandular stage (5–16 weeks), canalicular stage (16–26 weeks), saccular stage (26 weeks until term), and alveolar stage (postnatal stage).

Embryonic Stage

The lung originates from the laryngotracheal groove of the endoderm located at the fourth pharyngeal arch. The splanchnic mesoderm provides the muscular and cartilaginous covering to the lung and also forms the visceral pleura, while the somatic mesoderm forms the parietal pleura.[4] The laryngotracheal groove out-pouches from the foregut, forming the respiratory diverticulum that forms the tracheal bud separating it from the esophagus. The tracheal bud further branches into the two primary bronchi (left and right), which then divide into secondary or lobar bronchi (three bronchi on the right and two on the left for each lung lobe) by 5 weeks of gestation.

Pseudoglandular Stage

The lung continues to grow laterally and caudally on exposure to the splanchnic mesoderm. The conducting airways progressively branch until terminal bronchioles (16th- to 25th-generation

Figure 105-1 Classification of developmental disorders of the lung.

bronchioles) are formed by 16 weeks of gestation. Simultaneously, the mesenchymal tissue derived from the mesoderm starts to differentiate into ciliated columnar epithelial cells, goblet cells, and eventually type II pneumocytes.[5] This stage marks the transition between the conducting and the respiratory airways.

Canalicular Stage

Between 16 and 25 weeks of gestation, the epithelium differentiates into type I pneumocytes, also known as alveolar cells, which are the primary structural cells responsible for gas exchange.[6] There is extensive angiogenesis leading to the formation of the capillary network surrounding the alveolar cells. At the same time, lamellar bodies (inclusion bodies) start to form within the type II pneumocyte and are the primary sites for surfactant storage.[7] The conducting airways continue to elongate and grow in diameter, forming a canalicular appearance.

Saccular Stage

During this stage (26 weeks to term), there is progressive maturation of type I and type II pneumocytes and a decrease in interstitial tissue leading to the formation of air spaces. The air spaces are known as primary sacculi and are the location of future gas exchange.[8] There is an exponential growth in primary sacculi with the formation of the primary septum between each saccular unit. At this stage, the primary septa contain a double-layered capillary network.[7] The mesenchymal tissue also differentiates into smooth muscle cells and a fibroelastic network of collagen fibrils that are the foundation for the process of alveolarization.

Alveolarization Stage

This stage starts well before birth and continues into young adulthood as long as lung growth continues. The primary sacculi differentiate into alveoli, and the microvasculature continues to mature and consolidate, leading to a single-layered capillary network in the alveolar septa. This process occurs in an initial bulk alveolarization phase of rapid alveolar differentiation and microvascular maturation, and is followed by a slow continuous alveolarization phase where alveoli continue to differentiate and grow even up to the age of 20 years.[9] Interestingly, alveolarization has been observed even after pneumonectomy, explaining the compensatory growth of the contralateral lung.[10]

■ Role of Fetal Lung Fluid in Lung Development

During intrauterine lung growth, the bronchial tree is filled with protein-free, chloride-rich fluid known as fetal lung fluid. It has electrochemical properties distinct from amniotic fluid and plasma and plays a significant role in keeping the airways patent during lung development.[11] The accumulation of lung fluid provides the needed distension of 2 to 4 cm H_2O end expiratory pressure to keep the airways patent and allow for transfer of important growth factors and hormones to distant lung segments for morphogenesis and structured growth.[12]

Fetal lung fluid also plays a significant role as the fetus transitions from an intrauterine environment to the external environment. The lung epithelium switches from a predominantly secretory role to an absorptive role through alterations in sodium and chloride transporter channels. This facilitates rapid absorption of the lung fluid during birth and maturation of surfactant, thus allowing for gas exchange. A defect in absorption of lung fluid can lead to respiratory distress syndrome and transient tachypnea of the newborn.[13]

■ Molecular Mechanism of Lung Development

A complex interaction involving several growth factors and signaling molecules plays a significant role in lung morphogenesis and maturation at each stage of lung growth. The molecular pathways are tightly regulated to define right and left branching pattern, size of the airways, and the surface area participating in gas exchange. Dysregulation of any of these pathways may result in aberrant lung development.

HNF3β and homeobox genes 3 and 5 (Hoxa3 and 5) play a role in development of the laryngotracheal groove in the foregut endoderm.[14–16] Once the tracheal groove is formed, fibroblast growth factor 10 (FGF10) arising from the mesenchyme stimulates the foregut endoderm to initiate lung branching distal to the trachea. FGF10 is tightly controlled by thyroid transcriptional factor Nkx2.1, sonic hedgehog (Shh) pathway, and retinoic acid receptor (RAR).[17–19] A null mutation in these pathways may result in tracheal agenesis, tracheoesophageal fistula, and pulmonary hypoplasia.[20] A complex interplay between FGF10 and its inhibitory molecules determines the branching morphogenesis of the lung, with elevated FGF10 activity leading to airway branching at the lung tip and inhibition leading to arrest of further lung branching. Several other molecules including bone morphogenetic protein (BMP) family, epidermal growth factor (EGF), platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), membrane-associated protein (MAP), and surfactant protein-C among others play crucial roles in lung growth, vasculogenesis, cartilage and smooth muscle formation, and alveolarization.[21]

AIRWAY DISORDERS

A variety of developmental disorders of the airway are well recognized and are described below.

■ Tracheal Agenesis

Tracheal agenesis is a lethal malformation that results from the arrest of the lung bud during the embryonal stage of lung development. As a result, there is either complete absence or interruption of the trachea, which is generally incompatible with life. There are three types of tracheal agenesis, as described by Floyd et al. in 1962 (Fig. 105-2).[22] Type I tracheal agenesis is associated with the absence of the proximal trachea and the development of a distal tracheoesophageal fistula. Type II is characterized by the complete absence of the trachea, with normal bifurcating primary bronchi fused at the carina (most commonly associated with an esophagocarinal or esophagobronchial fistula). Type II is the most common subtype and accounts for 50% to 60% of all tracheal agenesis. Type III also is characterized by the complete absence of the trachea, but the individual primary bronchi branch out from the esophagus.

Tracheal agenesis is a rare disorder with a prevalence of 1:50,000 cases and has a male predominance (male:female ratio of 2:1).[23] Sonic hedgehog mutations in mice demonstrate similar defects, but no specific genetic mutation has been associated with tracheal agenesis.[24] It is commonly associated with other congenital abnormalities such as VACTERL (vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal and limb abnormalities) and TACRD (tracheal atresia/agenesis, cardiac defects, radial ray defect, and duodenal atresia).[25] In 70% of cases, tracheal agenesis is associated with polyhydramnios, respiratory distress, absent cry at birth, and inability to intubate beyond the vocal cords.[26]

Most neonates die within hours of birth, but temporizing methods such as esophageal intubation may be helpful in the presence of a distal tracheoesophageal fistula. With the availability of extracorporeal membrane oxygenation (ECMO), urgent cannulation and prompt surgical consultation can be considered. As a temporizing measure, tracheotomy with the insertion of a long T-tube has been described in type I tracheal agenesis.[27] Subsequently, esophageal reconstruction with colonic interposition graft can help prolong life.[27]

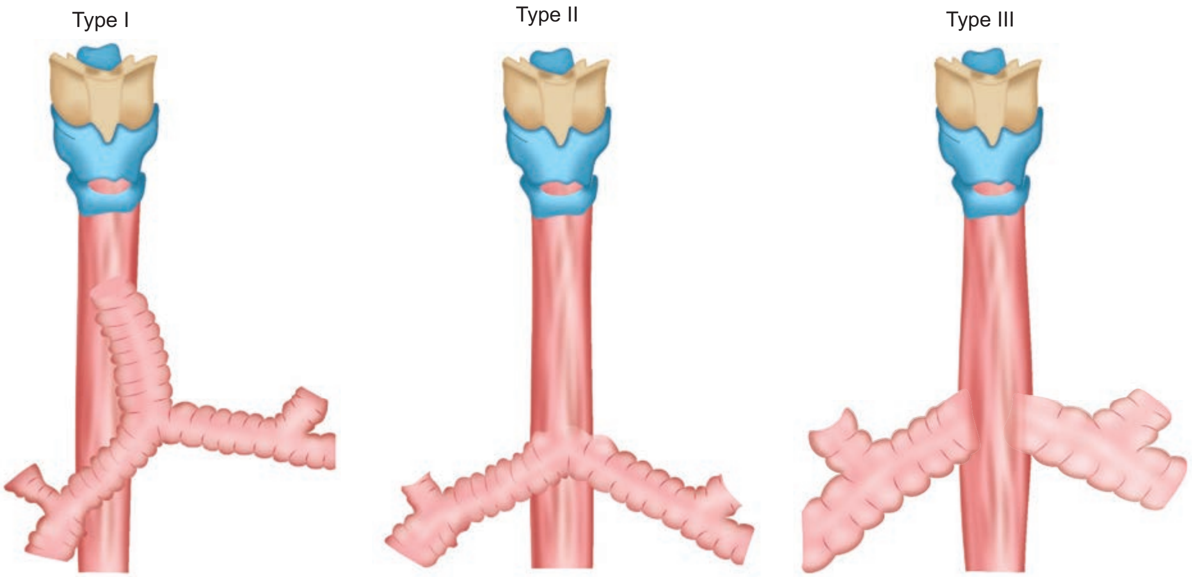

Figure 105-2 Types of tracheal agenesis. Schematic diagrams demonstrating three types of tracheal agenesis. Type I: Absence of proximal trachea with a distal tracheo-esophageal fistula. Type II: Complete absense of trachea with carina originating from the esophagus. Type III: Absence of trachea and carina with main bronchi originating directly from the esophagus.

Bronchial Atresia

Bronchial atresia is a congenital defect of a segmental or lobar bronchus leading to focal hyperinflation of the obstructed lung segment and compression of the adjacent segments. Bronchial atresia results from a defect in the vascularization of the bronchial bud and consequent termination of growth in the affected segment.[7] Collateral ventilation of the obstructed lung segment from adjacent normal lung segments via pores of Kohn leads to hyperinflation. Histopathology reveals an obstructed bronchus or bronchocele lacking communication with the bronchial tree and surrounded by hyperinflated alveoli.[28] The estimated prevalence of bronchial atresia is 1.2 cases per 100,000 and there is a male predilection.[29]

While most patients remain asymptomatic, bronchial atresia in the adult may manifest as recurrent pneumonias, atypical mycobacterial infection, or pneumothorax. The hyperinflated segment may compress the adjacent healthy segments leading to atelectasis. Recurrent infections can also lead to cavitary lung disease within the obstructed segment.[28,30]

Chest radiographs may reveal focal hyperlucency in a lung segment. A contrast-enhanced CT of the chest is the diagnostic modality of choice and demonstrates a tubular nonenhancing structure suggestive of mucus impaction in a segmental bronchus leading to an area of hyperlucent lung parenchyma (Fig. 105-3).[31] Adjacent atelectasis, cavitary lesions, and pneumothorax are other radiographic findings associated with bronchial atresia.

Management is driven by the severity of symptoms. Asymptomatic and mildly symptomatic patients can be managed conservatively with interval imaging to evaluate for complications. In patients with recurrent pneumonia or pneumothorax, surgical resection is the preferred modality. Lobectomy is preferred over segmentectomy as the hyperinflated segment often leads to chronic compressive atelectasis of the adjacent segments, which may not inflate after segmentectomy.[32,33]

Congenital Tracheobronchomegaly (Mounier-Kuhn Syndrome)

Congenital tracheobronchomegaly, also known as Mounier-Kuhn Syndrome (MKS), is a developmental disorder of the central airways characterized by pathologic enlargement of the trachea and up to fourth-order bronchi along with airway diverticula (Fig. 105-4). Generally, tracheomegaly is defined by tracheal diameter greater than 25 mm and 27 mm in transverse and sagittal sections, respectively, in men, and greater than 21 and 23 mm in transverse and sagittal sections, respectively, in women.[34] Bronchomegaly is defined as a transverse diameter greater than 21 mm for the right main bronchus (RMB) and 18.4 mm for left main bronchus (LMB) in

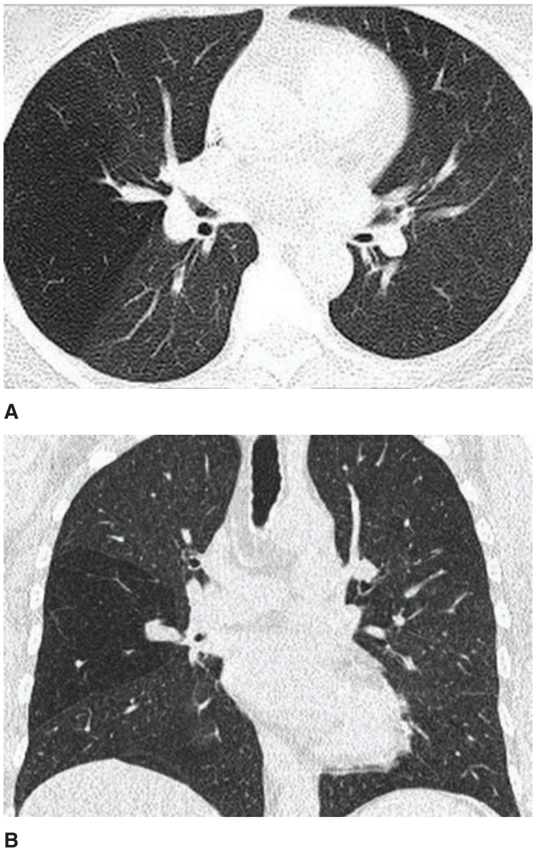

Figure 105-3 **A,B.** Bronchial atresia. Chest CT axial and coronal reformatted images show a proximal focal tubular-shaped opacity radiating from the hilum associated with a distal area of hyperlucent lung parenchyma in the right middle lobe.

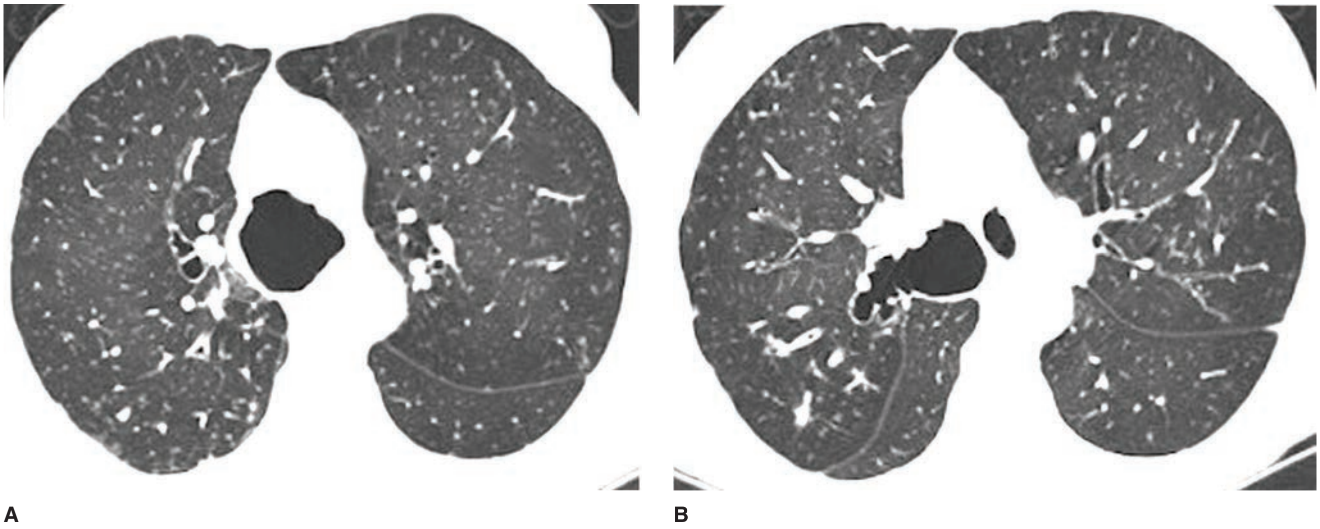

Figure 105-4 **A,B.** Mounier-Kuhn syndrome. Axial CT lung images show markedly dilated trachea and right main bronchus (left bronchus not shown).

males and 19.8 mm for RMB and 17.4 for LMB in females.[35] MKS is an extremely rare disorder with predominantly male preponderance (male:female ratio of 8:1). It is most often diagnosed in the third to sixth decade of adult life.[35,36] The pathogenesis of MKS is not well understood; however, atrophy of the smooth muscle layer and elastic cartilage have been demonstrated on histopathology, suggesting a mesenchymal defect during the saccular stage of lung development.[37] A similar congenital disorder known as William Campbell syndrome is characterized by bronchomegaly beyond the fourth order of bronchi and cystic bronchiectasis (Fig. 105-5).[38] Some familial cases of MKS have been reported in the literature suggesting a possible autosomal recessive mode of transmission.[39] Tracheobronchomegaly can also be an acquired defect in Ehlers-Danlos syndrome, Marfan syndrome, cutis laxa syndrome, Bruton disease, and Kenny-Caffey syndrome.[36]

MKS is classified into three anatomic phenotypes. Type I is characterized by mild symmetric dilation of central airways. Type II is characterized by variable dilation in the central airways along with the presence of diverticula. In type III, diverticula extend into the distal bronchi; this is usually the most severe form of MKS.[35,36]

Most patients with MKS remain asymptomatic until the third decade of life. Because of impaired airway clearance, recurrent lower respiratory tract infections are a prominent feature often leading to development of secondary bronchiectasis.[40,41] The diagnosis is often made incidentally on computed tomography (CT) of the chest. Expiratory-phase chest CT is recommended to evaluate for tracheobronchomalacia (TBM), which is common in MKS. Bronchoscopy reveals tracheobronchial dilatation, airway

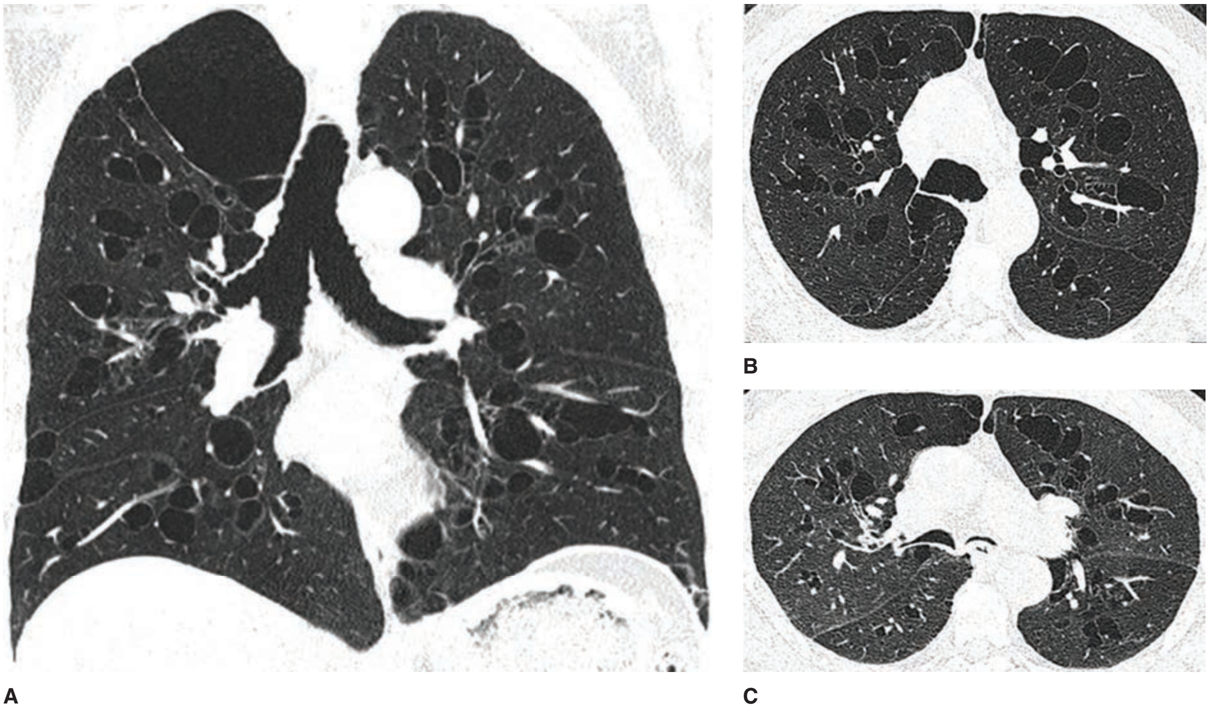

Figure 105-5 William-Campbell syndrome. HRCT of the lungs with coronal multiplanar reformation (**A**) and axial (**B**) images showing abnormally dilated middle order bronchi. Expiratory axial image (**C**) shows collapse of bronchiectatic airways. The trachea and major bronchi are normal in caliber. Note large right apical bulla (**A**).

diverticula, and expiratory collapse due to TBM but is not required for diagnosis. Pulmonary function testing may demonstrate an obstructive defect with air trapping.[40,41]

Treatment is chiefly supportive, focusing on airway clearance and antibiotics for acute respiratory tract infections. Suppressive inhaled antibiotics such as tobramycin may be effective in cases with *Pseudomonas aeruginosa* colonization and recurrent lower respiratory tract infections.[42] Since TBM is common, noninvasive positive-pressure ventilation has been used to facilitate airway clearance and treat chronic respiratory failure. In rare cases with severe TBM, silicone tracheal stents may be utilized.[43] Surgical tracheobronchoplasty for TBM and surgical resection of diverticula and sacculation have been successfully utilized in severe cases. Lung transplantation has been successfully performed in MKS patients with chronic respiratory failure.[44]

■ Tracheobronchial Branching Abnormalities

Early in fetal life, the lung bud starts to branch caudally and distally, forming segmental and subsegmental branching by the sixth week of gestation.[45] Several anomalies in tracheobronchial branching can occur and are classified according to their anatomic relationship to the ipsilateral pulmonary artery.[46] The normal right upper lobe bronchus is eparterial—that is, it arises above the point where the right pulmonary artery crosses the right main bronchus. An anomalous right bronchus arising from the right main bronchus above the point of crossing with the artery is pre-eparterial, and one that arises distal to the origin of the right upper lobe bronchus is post-eparterial. The normal left upper lobe bronchus is hyparterial, as it courses below the point where the left pulmonary artery crosses the left main bronchus. Anomalous bronchi arising from the left main bronchus above and below above the point of crossing with the left pulmonary artery are called left eparterial and pre-hyparterial bronchi, respectively, while an anomalous left bronchus that arises distal to the origin of left main bronchus is called post-hyparterial.[46,47]

The most common tracheobronchial anomalies include the tracheal bronchus, cardiac bronchus, and two types of bridging bronchi (type I and type II).

Tracheal Bronchus

The tracheal bronchus is characterized by an abnormal origin directly from the trachea (Fig. 105-6). Most tracheal bronchi are displaced upper lobe bronchi (88%) and rarely supernumerary (12%), with the ventilated lobe known as the tracheal lobe.[48] The prevalence of right tracheal bronchus is 0.1% to 2% and 0.3% to 1% for left tracheal bronchus.[49,50] The tracheal bronchus is frequently associated with congenital heart disease, Down syndrome, tracheal stenosis, or tracheoesophageal fistula.[51,52]

Both supernumerary and displaced tracheal bronchi arise directly from the trachea. A supernumerary bronchus coexists in addition to normal branching upper lobe bronchi, while a displaced bronchus is an aberrant bronchus that replaces one missing branch of the upper lobe bronchus. For example, the most common displaced tracheal bronchus supplies the apical segment of the right upper lobe, with the right upper lobe bronchus dividing into an anterior and posterior division (i.e., the apical division is absent). The supernumerary bronchus is an extra bronchus (in addition to the normal corresponding bronchi for the lobe) that may end in a blind pouch, diverticula, or ventilated or unventilated parenchyma.[47] It should be distinguished from a tracheal diverticulum. The patients may present with recurrent pneumonia of the tracheal lobe or supernumerary lobule. Most cases are identified incidentally on imaging or bronchoscopy.

Cardiac Bronchus

A supernumerary bronchus called cardiac bronchus originates from the medial wall of the right main bronchus or bronchus intermedius and is directed towards the heart and carina. A cardiac bronchus usually ends in a blind diverticular pouch but may supply an underdeveloped lobule. The cardiac bronchus is very rare, with a prevalence of 0.07% to 0.5%.[53] Most patients are asymptomatic and are identified incidentally on imaging or bronchoscopy. Symptomatic patients may experience dyspnea, recurrent lower respiratory tract infections in the underdeveloped, poorly ventilated lobule, and hemoptysis.[54] Chest CT with contrast can reveal the cardiac bronchus with contrast enhancement of unventilated lobule/tissue mass (Fig. 105-7). The ventilated lobule can be distinguished by an accessory fissure.[54]

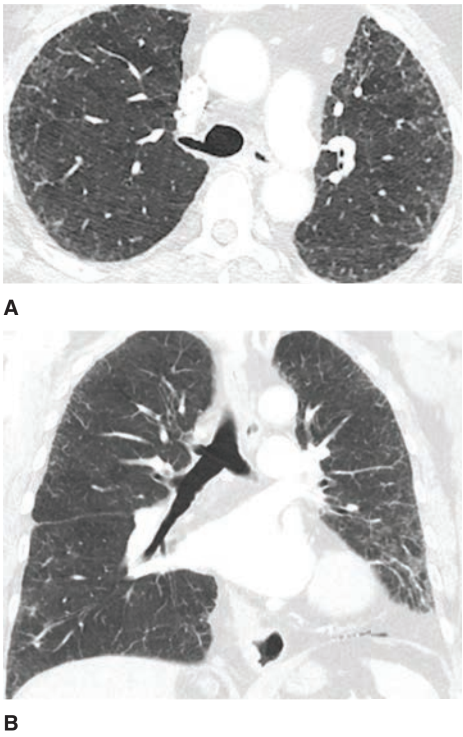

Figure 105-6 Right tracheal bronchus. Axial (**A**) and coronal multiplanar reformatted (**B**) CT images show a displaced tracheal bronchus that arises from the right lateral wall of the trachea and supplies the right upper lobe apical segment.

Intervention is rarely required, but surgical resection is a consideration in cases of massive hemoptysis or recurrent infections. Rare instances of malignancy arising from the tissue mass associated with a cardiac bronchus have been reported.[55]

Bridging Bronchus

In rare instances, the airways of the right lung may originate from the left main bronchus rather than the carina. Two types of bridging bronchi have been described (Fig. 105-8). Type I bridging bronchus originates from the left main bronchus and supplies the right middle and lower lobe, whereas the right upper lobe bronchus originates from the carina. Type II bridging bronchus is characterized by a blind right-sided pouch at the carina and the right main bronchus originating from the left main bronchus.[47] The bridging bronchus is frequently associated with left pulmonary artery sling and tracheal stenosis.[56] The outbranching of the right main bronchus from the left (pseudocarina) may be mistaken as the primary carina on bronchoscopy. A chest radiograph or CT may show the pseudocarina to be much lower (T6–T8) compared with the primary carina (usually T4–T5) and aids in diagnosis of bridging bronchus, especially type II phenotype.

The most common symptoms include wheezing and dyspnea due to tracheal stenosis.[57] Management is usually surgical if a long segment tracheal stenosis is present. Modified end-to-end anastomosis

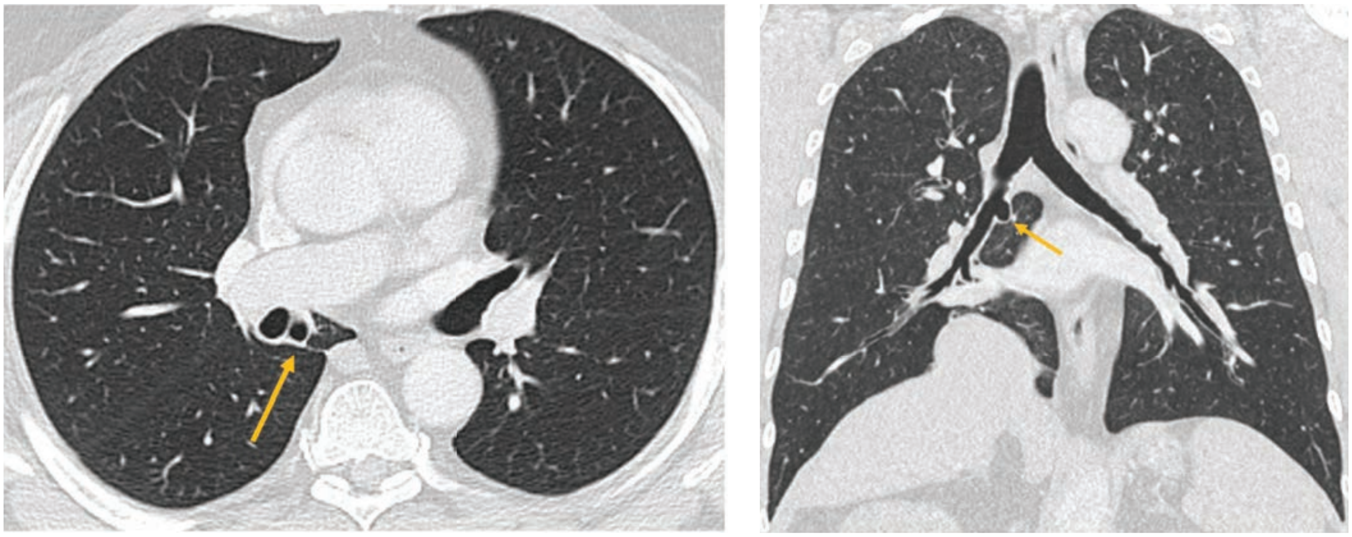

Figure 105-7 Cardiac bronchus. Axial (**A**) and coronal reformatted (**B**) CT lung images demonstrate a rudimentary bronchus *(cardiac bronchus)* that arises from the bronchus intermedius and ends in a blind pouch *(arrows)*.

technique has been described for tracheal stenosis with bridging bronchus.[58] Alternatively, slide tracheoplasty has been successfully performed for long-segment stenosis. The stenosed segment is transected at midpoint; the upper segment is incised posteriorly and lower segment anteriorly. The dissected segments are trimmed, slid together, and sutured to create a larger circumference for the trachea.[59,60]

■ Bronchogenic Cyst

A bronchogenic cyst is a congenital anomaly that is derived from the lung bud of the foregut in the embryonal stage of lung development. It is characterized by a fluid-filled blind cystic pouch, in either the mediastinum or the lung parenchyma. The location is dictated by the stage of embryonic development at which the defect occurs; defects early in lung development result in mediastinal cysts while defects in the later phase of lung development result in cysts in the lung parenchyma, predominantly in the lower lobes.[61,62] Most common locations in the mediastinum include the paratracheal, subcarinal, paraesophageal, and hilar regions. These cysts may rarely be found along the pleura, diaphragm, and neck. The incidence of bronchogenic cyst is estimated to be 1 in 42,000 to 68,000 hospital admissions and carries a male predilection.[63]

Patients are often asymptomatic, but symptoms secondary to compression of mediastinal structures can lead to superior vena cava syndrome, dyspnea, or dysphagia.[64] Postobstructive pneumonia and infection of the intrapulmonary cyst can occur in 82% of the cases who present with persistent cough, purulent expectoration, recurrent fevers, chest pain, or hemoptysis.[61,65]

A chest radiograph may demonstrate a parenchymal ovoid structure with a sharp border and occasionally an air–fluid level, resembling a lung abscess. A mediastinal bronchogenic cyst can be identified as an ovoid structure in the middle mediastinum on a lateral chest radiograph. Chest CT is the imaging modality of choice to identify bronchogenic cysts. The density (in Hounsfield units) of the cyst on CT may range from that of water to soft-tissue content and may contain calcium precipitate as well (known as milk of calcium) (Fig. 105-9).[66] Magnetic resonance imaging (MRI) may be utilized for surgical planning to differentiate surrounding structures. The bronchogenic cyst does not enhance with contrast, and the cystic content may have a variable intensity signal on T1-weighted images depending on proteinaceous debris, while T2-weighted images will demonstrate high intensity.[66] Based on imaging, the differential diagnosis may include a hydatid cyst (has typical septations within the cyst) and cystic teratomas (inhomogeneous, fat-containing, and present in anterior mediastinum) for mediastinal cysts; the differential diagnosis may include infected bullae, lung abscess, vascular malformation, and tuberculous cavity for intrapulmonary cysts.[65] Histopathology on surgically resected cyst provides the most definitive diagnosis and demonstrates characteristic respiratory ciliated pseudostratified columnar epithelial cells with the presence of occasional calcification, bronchial glands, smooth muscles, and cartilage in the cyst wall.[63]

Asymptomatic bronchogenic cysts are usually managed conservatively. Mediastinoscopy, transbronchial needle aspiration (TBNA), or biopsy of the cyst wall may be considered for diagnosis (Fig. 105-10).[67]

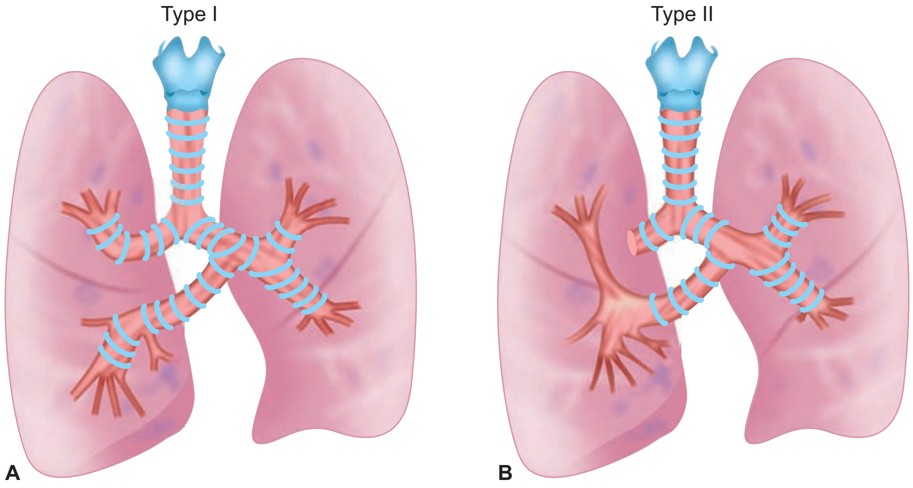

Figure 105-8 **A,B.** Two types of bridging bronchus. Schematic diagram demonstrating two types of bridging bronchus. Type I: The right bridging bronchus originates from the left main bronchus and supplies the right middle and lower lobes. The right upper lobe bronchus originates from the carina. Type II: The right bridging bronchus originates from the left main bronchus and supplies the entire right lung. The right main bronchus ends in a blind pouch.

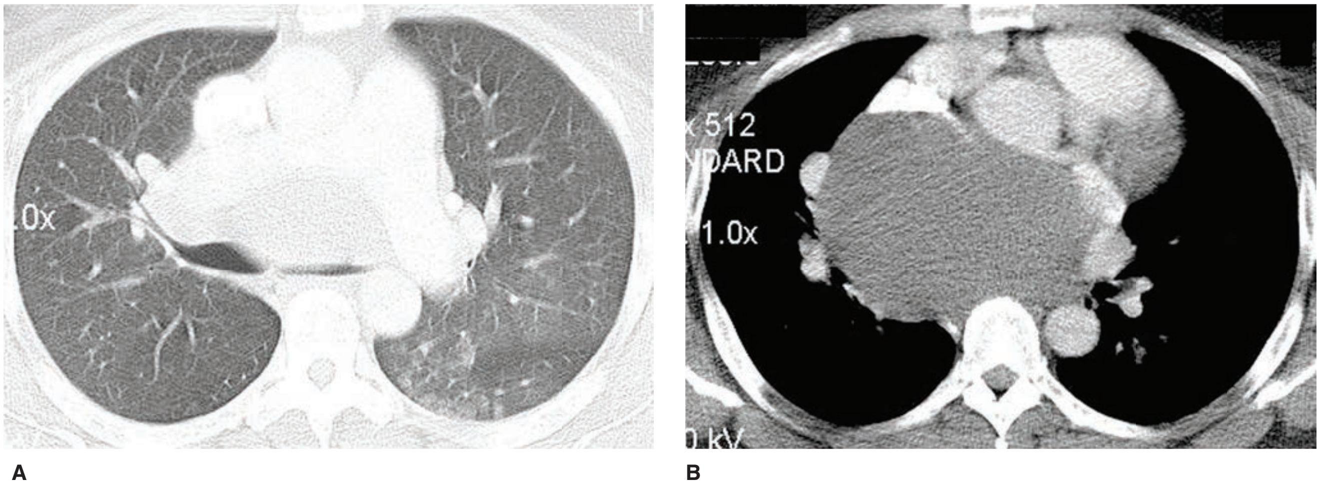

Figure 105-9 Bronchogenic cyst. Chest CT axial images at and just below the carinal level in lung window (**A**) and mediastinal window (**B**) settings show a large subcarinal cystic lesion causing mass effect on the left main bronchus and left atrium.

If the patient is symptomatic, a cyst-related complication such as postobstructive pneumonia or infected cyst must be excluded. While treatment is usually surgical excision, successful bronchoscopic drainage via transbronchial approach has been described and offers a less invasive therapeutic approach to mediastinal bronchogenic cysts.[68] Video-assisted thoracoscopic surgery (VATS) is the treatment of choice,[69,70] but posterolateral thoracotomy may be required for a large, complicated bronchogenic cyst. For intrapulmonary bronchogenic cysts, VATS cystectomy, wedge resection, segmentectomy, or lobectomy may be required depending on the size, location, and complications such as recurrent pneumonia with frequent hospitalizations.[70,71] The recurrence rate is usually low with complete resection, but cysts may recur if residual mucosa is left in the mediastinum.

■ Congenital Pulmonary Airway Malformation (CPAM)

Congenital pulmonary airway malformation (CPAM), previously known as congenital cystic adenomatoid malformation (CCAM), is characterized by cystic hamartomatous lesions in the lung. CPAM is a rare disorder with a prevalence of 9 cases per 100,000 total births.[72] The pathogenesis is believed to be due to abnormal branching of primitive bronchioles resulting in arrested development at various stages of lung morphogenesis. The primary insult appears to take place during the pseudoglandular stage but can occur as late as the alveolarization stage resulting in more distal cystic lesions.[73] Hoxb5 is required for lung branching morphogenesis during the pseudoglandular stage of lung development, and its expression subsequently decreases in advanced stages.[74] Overexpression of the Hoxb5 gene beyond the pseudoglandular stage has been implicated

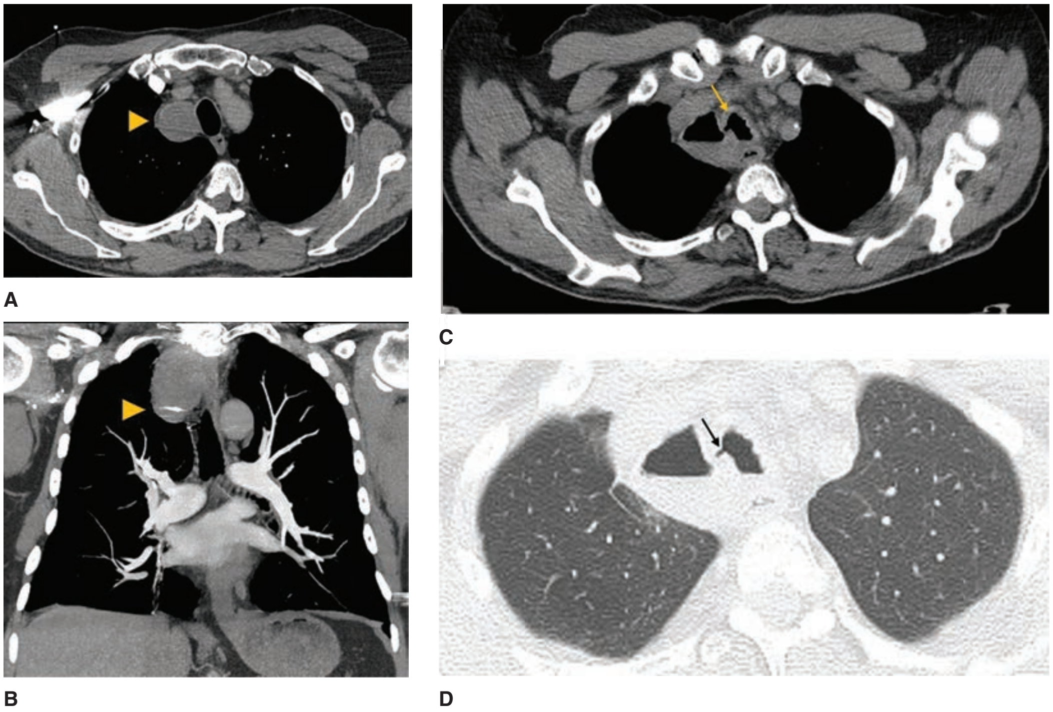

Figure 105-10 Bronchogenic cyst. Chest CT angiography axial image at the level of the great vessels (**A**) and coronal maximum-intensity projection image (**B**) show a well-circumscribed cystic mass in the right paratracheal region without any solid mural enhancing component *(arrowheads)*. Endotracheal cyst drainage was performed. Postprocedure (bronchoscopic cyst drainage) unenhanced chest CT axial images in mediastinal (**C**) and lung (**D**) window settings show an air–fluid level in the cyst with a fistulous tract to the right lateral wall of the trachea *(arrows)*.

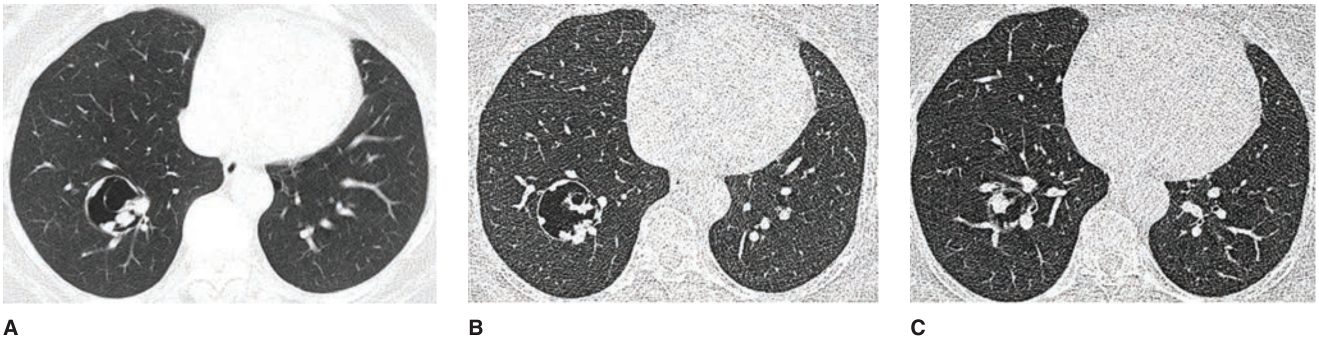

Figure 105-11 CPAM. Routine (**A**) and inspiratory HRCT (**B**) lung images show a relatively thin-walled cystic mass in the right lower lobe with mural nodular densities and a smaller cyst within the cyst, which remained stable over 10 years. Expiratory HRCT image (**C**) demonstrates partial decompression of the cyst suggestive of airway communication.

in the development of CPAM.[74] Overexpression of the human keratinocyte growth factor (KGF/Fgf7) gene and platelet-derived growth factor B (PDGFB) also have been associated with CPAM.[75,76]

Up to 70% of CPAM present as cystic lesions in distal bronchi; however, a subset may present as soft tissue masses (Fig. 105-11). As a result, the nomenclature was changed from CCAM to CPAM with classification of CPAM into five subtypes by Stocker et al.[77] Type 0 occurs at the tracheal or primary bronchial level and is often lethal. Type 1 is the most common type of CPAM, accounting for 50% to 70% of all cases, arising from distal bronchus and often presenting as a single large (3–10 cm) cyst with significant mass effects on adjacent organs (Fig. 105-12). Type 2 is the second most common, accounting for 15% to 30% of all cases. Type 2 CPAMs arise from the terminal bronchioles and typically present as evenly spaced small cysts (1–2 cm), often with solid components. Type 2 CPAM is often associated with extrapulmonary anomalies such as renal agenesis, cardiac defects, gastrointestinal atresia, and skeletal abnormalities.[78] They can be radiographically challenging to distinguish from, and indeed can be associated with, extralobar pulmonary sequestration (hybrid lesions).[78] The presence of a systemic blood supply in pulmonary sequestration helps in distinguishing the two entities.[78] Type 3 CPAM is characterized by “micro cysts” (<5 mm) consisting of cuboidal epithelium similar to fetal lung and appears largely solid on CT. Type 4 CPAM also develops from the alveolar tissue and can be indistinguishable from type 1 CPAM on imaging, characterized by very large peripheral cysts (10 cm), risk of pneumothorax, and mass effect. Malignant transformation is known to occur with CPAM. Types 1 and 2 are precursors with potential for mucinous adenocarcinoma and rhabdomyosarcoma formation, respectively.[79] Type 2 and type 4 CPAM can be associated with pleuropulmonary blastoma.[80]

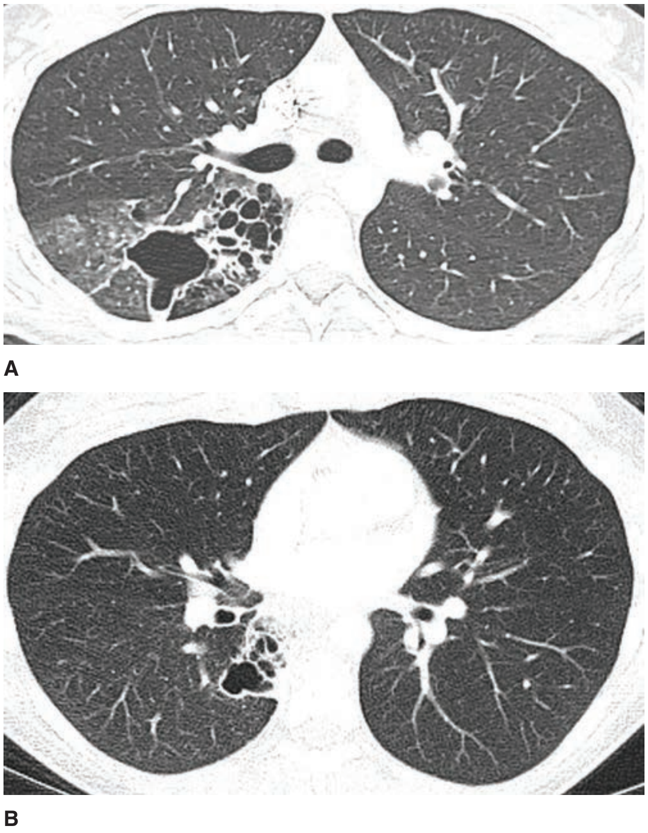

Figure 105-12 CPAM. HRCT lung images (**A, B**) demonstrate a unilocular 5.5-cm cyst surrounded by smaller cysts in the superior segment right lower lobe, suggestive of type 1 CPAM.

With the advent of frequent antenatal monitoring and obstetric ultrasound, most cases of CPAM are identified prior to birth. Without intervention, fetal hydrops in the presence of CPAM develops in up to 40% of cases and is associated with high mortality.[81] Prenatal obstetric ultrasound has a sensitivity of 93% and specificity of 32% for detecting CPAM. Fetal MRI is superior in identifying systemic feeding vessels to differentiate CPAM from BPS (sensitivity of 71%, specificity of 88%).[82] The likelihood of detection is high in the first trimester as the fetal lungs become more echogenic in later stages of development, making it challenging to identify this abnormality. Up to a third of CPAMs identified in early pregnancy resolve spontaneously before birth.[72] Up to 50% of neonates with CPAM are asymptomatic at birth and can be managed expectantly. If elective surgical resection is considered, it should be performed within 10 months of birth as it is associated with fewer complications.[83]

The decision to surgically resect a lesion in prenatal or early neonatal phase takes into account the risk of malignant transformation of existing lesions. Although type I and type II subtypes of CPAM have been associated with malignancy such as pleuropulmonary blastoma and mucinous adenocarcinoma, there is a diagnostic challenge to clinically distinguish between a malignant lesion and a benign CPAM lesion without histologic examination. Several studies have demonstrated increased mucinous cell collections in patients with type I CPAM, which may predict future risk of mucinous adenocarcinoma.[84,85] Chromosomal aberration in chromosome 2 and 4 in the atypical goblet cells and oncogenic K-ras mutations have been identified in mucinous adenocarcinoma associated with type I CPAM.[86–88] Malignant transformation is largely reported in neonates compared with adults, and the reason may be that the large lesions in type I CPAM are symptomatic early in life and often intervened in early childhood. Future risk of malignancy in adults with developmental disorders still needs to be explored.

TABLE 105-1 Types of Bronchopulmonary Sequestration (BPS)

Type of BPS	Intralobar BPS	Extralobar BPS
Origin	Originates before pleural formation, often acquired after an infection	Originates after pleural formation, associated with other congenital abnormalities
Pleural covering	Does not have its own visceral pleura	Has its own visceral pleura
Common locations	Left lower lobe, right lower lobe, and rarely upper lobes	Left hemithorax, right hemithorax, anterior or posterior mediastinum, subdiaphragmatic, and neck
Association with CPAM	Less common	More common
Lower respiratory tract infection	More common	Less common
Venous drainage	Pulmonary or systemic	Always systemic

While many cases are detected through routine prenatal screening, CPAM is occasionally encountered in adult patients. They typically come to attention as an incidental finding on imaging performed for unrelated reasons or as a cause of recurrent lower respiratory tract infections or pneumothorax. Aspergillomas can form in pre-existing cavities and can result in life-threatening hemoptysis.[89] Asymptomatic adults do not require intervention, but patients with type I or type IV CPAM should be followed closely with interval imaging as there is slightly increased risk of malignant transformation.[87] The main indication for surgical resection in the adult is recurrent infections.

Bronchopulmonary Sequestration

Bronchopulmonary sequestration (BPS) is the second most commonly identified developmental disorder of the lung, accounting for up to 6.4% of all congenital pulmonary malformation.[90] It usually presents as a lung mass that has no communication with the tracheobronchial tree and does not actively participate in respiration. BPS is supplied by systemic arterial circulation, commonly branches of the thoracic (75%) and abdominal aorta (25%).[90,91] The venous drainage can be either pulmonary or systemic. Systemic venous drainage has been associated with a higher incidence of polyhydramnios, hydrops, and congenital anomalies such as skeletal dysplasia, cardiac anomalies, and diaphragmatic hernia.[92] BPS is hypothesized to originate from a supernumerary lung bud, and the location depends on its relation to the development of the pleura.[93]

BPS is classified into two types—intralobar BPS and extralobar BPS—based on its location. If the abnormal lung bud originates before the pleural formation, it migrates caudally with the true lung bud and appears as an intralobar BPS within the lung parenchyma. If it originates in later stages after pleural formation, it presents as an extralobar BPS and has its own visceral pleura. Intralobar BPS usually appears as a lung mass, most commonly located in the left lower lung (60%), right lower lobe (38%), and rarely in the upper lobes (2%) and does not have its own pleura.[91] Extralobar BPS can present in the left hemithorax (48%), right hemithorax (20%), anterior (8%) or posterior mediastinum (6%), and subdiaphragmatic area (18%).[94] Up to 50% of extralobar BPS are associated with coexisting CPAM, commonly type 2.[94] Table 105-1 highlights the differences between extralobar and intralobar BPS.

BPS is commonly identified during the second trimester on prenatal ultrasound as solid, homogenous, well-defined lesions with increased echogenicity.[95] A color Doppler is used to identify the systemic origin of the feeding artery, which is the characteristic feature of a BPS. On MRI, it appears as a homogenous, well-defined mass with higher signal intensity than the lung but lower intensity than the amniotic fluid on T2-weighted imaging. Since most BPS (71% intralobar and 94% extralobar) decrease in size or regress before birth, they may become isoechoic on ultrasonography and isointense on MRI beyond 28 weeks of gestation.[96] In adults, a CT scan of the chest with angiography is the imaging modality of choice, demonstrating a consolidation/mass with occasional cystic or emphysematous changes predominantly in the left lower hemithorax with an easily identifiable feeding systemic artery (Fig. 105-13).[97]

Most cases are asymptomatic at birth but can present as respiratory distress. Recurrent lower respiratory tract infections are more common with intralobar BPS (71%) compared with extralobar BPS (31%).[91] Often, BPS remains undiagnosed until adolescence or adulthood, when it may present as recurrent pneumonias. Up to 50% of adults are asymptomatic, with the BPS identified incidentally on thoracic imaging.[98]

When asymptomatic, small BPS can be managed conservatively; surgical resection with minimally invasive VATS between 6 and 12 months of postnatal life should be considered for larger lesions and symptomatic patients. Antenatal intrafetal vascular laser ablation of the feeding artery is an emerging technique that led to a reduction in the size or complete resolution of BPS in 92% of cases in a small series of 12 patients.[99] In adults, the most common indication for surgical resection is recurrent infection.[98]

PARENCHYMAL DISORDERS

In addition to developmental disorders of the airways, a variety of developmental disorders of the pulmonary parenchyma have been reported and are described below.

Congenital Lobar Emphysema

Congenital lobar emphysema (CLE), also called congenital lobar overinflation, is a rare disorder characterized by overdistension of a focal segment or lobe of the lung. CLE occurs in 1 in 20,000 live births, accounting for 10.5% of all developmental disorders of the lung, and is more common in males.[100,101] Several pathogenic mechanisms have been proposed in the development of CLE, such as focal cartilage defect theory and polyalveolar theory. Focal defect or absent bronchial cartilage may result in dynamic airway collapse and air trapping, eventually leading to the formation of an overdistended lobe in up to 25% cases.[102] Morphologically there is no tissue damage; however, there is a disruption in the maturation of the acini postpartum in the affected airways leading to primitive acini with overdistended alveoli. The polyalveolar theory was proposed by Hislop and Reid in 1970 when they found a fivefold increase in the number of normal alveoli in a 17-day-old neonate without overdistension, suggesting a form of alveolar gigantism.[103] Several other case series demonstrated alveolar hyperplasia in their cohorts, supporting this pathogenetic mechanism. Demonstration of a higher-than-expected (for age) radial alveolar count has been suggested as a method for pathologic diagnosis of a polyalveolar lobe.[104,105]

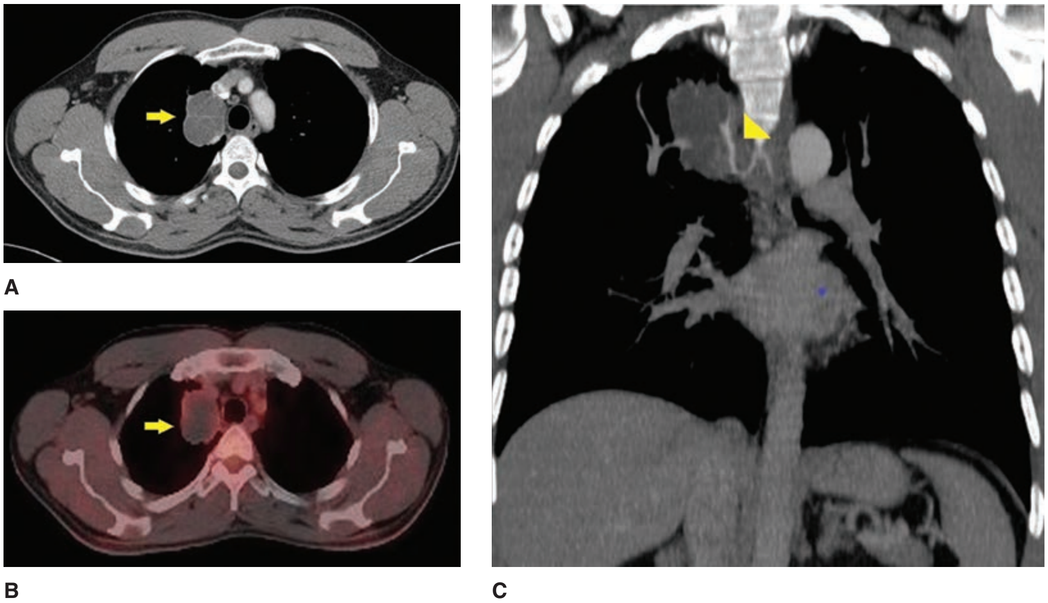

Figure 105-13 Intralobar sequestration. Contrast-enhanced chest CT (**A**) shows a well-circumscribed right paratracheal cystic mass of indeterminate etiology *(arrow)*. (**B**) PET-CT scan shows no significant FDG uptake, suggesting no hypermetabolic malignancy or active infection/inflammation. (**C**) Coronal maximum-intensity projection image shows abnormal feeding systemic artery from the descending aorta coursing into the right upper lobe soft tissues *(arrowhead)*, confirming sequestration. The feeding artery distinguishes the lesion from a bronchogenic cyst.

Other developmental disorders can mimic CLE by causing extrinsic bronchial compression and unilateral lobar hyperinflation. These include bronchial stenosis, meconium aspiration syndrome, foreign body aspiration, bronchial polyp, bronchogenic cyst, and pulmonary artery sling anomaly.[106]

Most cases of CLE are identified in the early neonatal period due to symptoms of cough, respiratory distress, or wheezing. Asymptomatic cases can go undiagnosed until adulthood and can be diagnosed incidentally on chest imaging.[107] CLE may be associated with cardiac anomalies such as ventricular septal defect, atrial septal defect, and tetralogy of Fallot.[108]

Chest radiography demonstrates focal lobar hyperlucency with contralateral mediastinal shift (Fig. 105-14).[109] The presence of bronchovascular markings within the hyperlucent area can help differentiate the overdistended lobe from pneumothorax or a cyst.[110] The left upper lobe is the most commonly affected site (42%–57%), followed by the right middle lobe (27%–35%) and right upper lobe (14%–30%).[111–113] Involvement of lower lobes or more than two lobes is rare but has been described in literature.[114,115] Chest CT demonstrates focal lobar or segmental overdistension with pulmonary vessels traversing through the affected lobe and compressive atelectasis of adjacent lung (Fig. 105-15). Mediastinal shift and, rarely, herniation of affected lung to the contralateral side also can be observed.[111] Pulmonary function tests often are normal,[105,116] but reduced forced vital capacity and forced expiratory flows at low lung volume and elevated residual volume can be demonstrated in severe cases.[117] Radionuclide ventilation–perfusion (V/Q) scan may be used for surgical planning and often shows reduced ventilation and perfusion to the affected lobe.[111]

Surgical resection is indicated for infants and children with respiratory distress. Asymptomatic or mildly symptomatic patients can be managed conservatively with close follow-up and repeat imaging.[113] Small case series have demonstrated conservative management to be noninferior to surgical treatment, as lung growth was found to be similar in both groups.[117] Since most adult patients either have mild symptoms or are diagnosed incidentally, they can be managed conservatively.

Pulmonary Hypoplasia

Pulmonary hypoplasia is a rare disorder resulting in arrested lung development. It is defined as a ratio of inflated lung volume to body weight below the 10th percentile for a given age group. Pathologically, radial alveolar count can be used to suggest pulmonary hypoplasia. Radial alveolar count is the number of alveoli from the center of the respiratory bronchiole to the nearest septal division

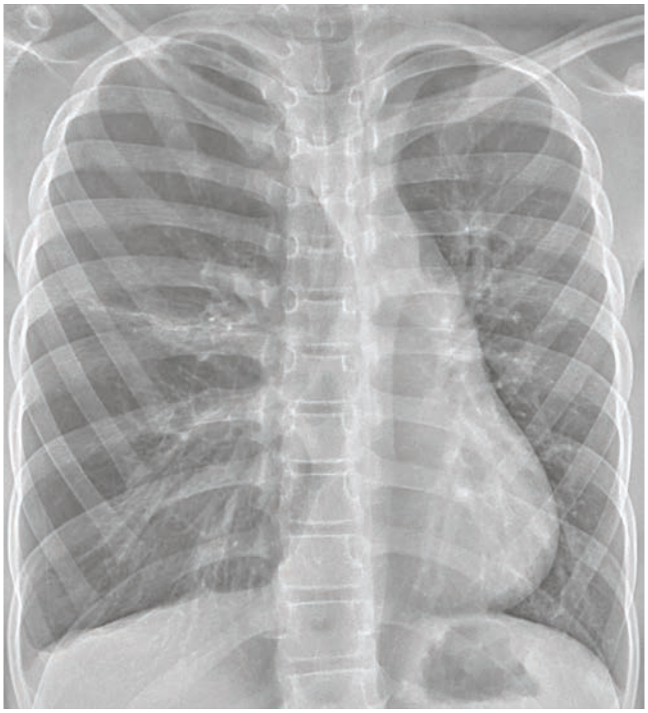

Figure 105-14 Congenital lobar emphysema. Chest radiograph demonstrates hyperlucent and overinflated right upper and middle lobe with compression atelectasis of the right lower lobe.

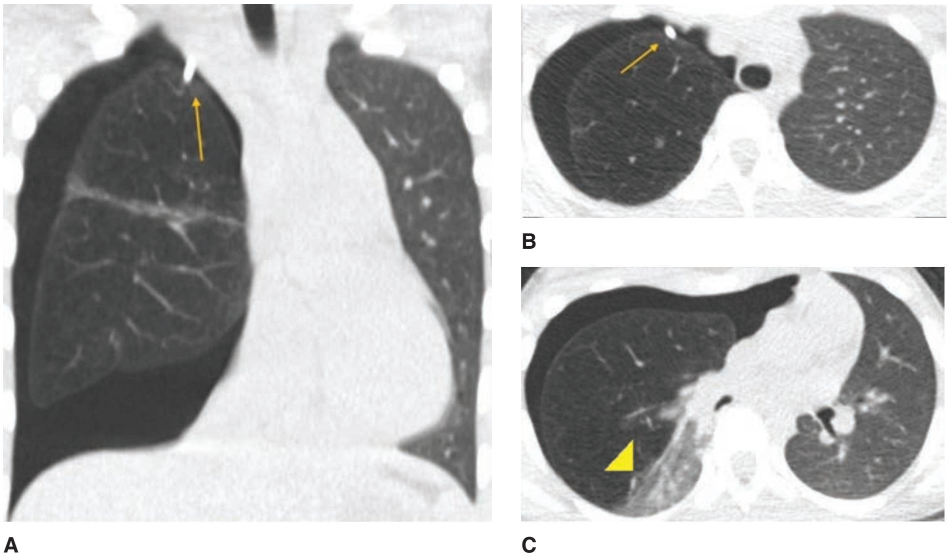

Figure 105-15 Congenital lobar emphysema (same patient as Fig. 105-14). Lung CT with coronal reformatted image (**A**) and axial images (**B, C**) shows hyperlucent and overinflated right upper and middle lobe with compression atelectasis of right lower lobe *(***C***, arrowhead)*. Note mediastinal shift. The affected right lung is larger than the normal left lung. There are decreased lung markings in the affected right lung in comparison to the normal left lung. A right pneumothorax is visualized with a pleural drain *(arrow)*.

transected by a perpendicular line. It is often used to assess lung development on biopsy samples.[118] A radial alveolar count ≤4.1 is suggestive of pulmonary hypoplasia on biopsy.[119] Previously, a ratio of lung weight to body weight less than 0.12 was also used to define pulmonary hypoplasia.[120]

The presence of lung fluid and fetal breathing movements play a significant role in lung development, and abnormalities such as oligohydramnios, decreased lung fluid, or absent fetal breaths can lead to pulmonary hypoplasia. As the elastic tissue and muscular layers develop in the airways, the lung fluid volume increases, leading to distending pressure necessary for stimulation of growth factors, cellular proliferation, and lung morphogenesis.[7] In animal models, fetal tracheostomy and lung fluid removal have resulted in pulmonary hypoplasia.[121] Oligohydramnios and premature rupture of the membrane during the canalicular phase of lung development may lead to the efflux of lung fluid due to decreased amniotic fluid. This leads to a decrease in distending pressures in the lumen of the lung and inhibition of lung growth and cellular proliferation.[122,123] Pulmonary hypoplasia is also observed in patients with congenital diaphragmatic hernia (CDH), as abdominal organs can compress the lung during pseudoglandular phase and inhibit lung branching and morphogenesis.[124] Other associated causes include renal agenesis (Potter syndrome) leading to oligohydramnios. In addition, kidneys grow in a similar fashion by branching morphogenesis and may share common signaling pathways as lungs and lead to development of renal and pulmonary hypoplasia.

With the advent of prenatal ultrasonographic screening, pulmonary hypoplasia can be diagnosed in utero. Common ultrasonographic parameters predictive of pulmonary hypoplasia include reduced thoracic circumference to abdominal circumference ratio, low lung area (correlates well with lung weight), and lung to head ratio (in cases of CDH).[125]

After birth, the most common symptoms include neonatal respiratory distress, cough, and recurrent lower respiratory tract infections. Often, patients are asymptomatic as the healthy lung compensates for the undeveloped lung. Adults with hypoplastic lung may present with chronic cough, recurrent pneumonia, and hemoptysis.[126] While most lung aplasia and agenesis do not survive to adulthood, lung hypoplasia is commonly identified incidentally on imaging. Chest imaging demonstrates a hyperexpanded healthy lung with a mediastinal shift toward the affected side. The hypoplastic lung may appear shrunken, consolidated, cystic, or bronchiectatic. In areas endemic for tuberculosis, pulmonary hypoplasia may be misdiagnosed as tuberculosis due to similarity in chest imaging.[127] Chest CT is important to distinguish between pulmonary agenesis, aplasia, and hypoplasia. The absence of any rudimentary ipsilateral bronchus and lung parenchyma suggests agenesis, while presence of rudimentary bronchus in the absence of lung parenchyma suggests aplasia. In pulmonary hypoplasia, there is a rudimentary bronchus along with a small lung parenchyma (Fig. 105-16). In addition, the reduced size of the ipsilateral pulmonary artery may point toward underlying pulmonary hypoplasia.

Proactive detection and treatment of oligohydramnios may prevent the development of pulmonary hypoplasia. Autologous amniotic fluid–derived stem cell transplantation has been shown to augment lung growth in animal models and may offer potential therapeutic benefit in pulmonary hypoplasia. A prospective, randomized, controlled pilot study demonstrated the feasibility of amnioinfusion (serial infusions of saline or lactated Ringer's to maintain amniotic fluid volume) for premature rupture of membranes, although the small sample size precluded assessment of the impact on outcomes such as incidence of pulmonary hypoplasia.[128] Lung protective ventilation and the use of inhaled nitric oxide may have a potential role in improving oxygen indices in newborns with pulmonary hypoplasia.[129,130] In adults, bronchiectasis and recurrent lower respiratory tract infections are common in the hypoplastic lung and may lead to significant symptom burden and diminished quality of life. Good airway clearance measures such as saline nebulization and chest percussion therapy are often helpful to minimize infections. In some cases, suppressive inhaled antibiotics may be needed if pseudomonal colonization is detected. In cases of recurrent pneumonia, cavitary lesions, or significant symptom burden, pneumonectomy of the hypoplastic lung may lead to improvement in symptoms and quality of life.[126]

■ Pulmonary Cystic Mesenchymal Hamartoma

Pulmonary cystic mesenchymal hamartoma is an extremely rare developmental disorder of the lung composed of immature mesenchymal cells that gradually form multiple bilateral cysts and nodules. An imbalance between respiratory endoderm and surrounding

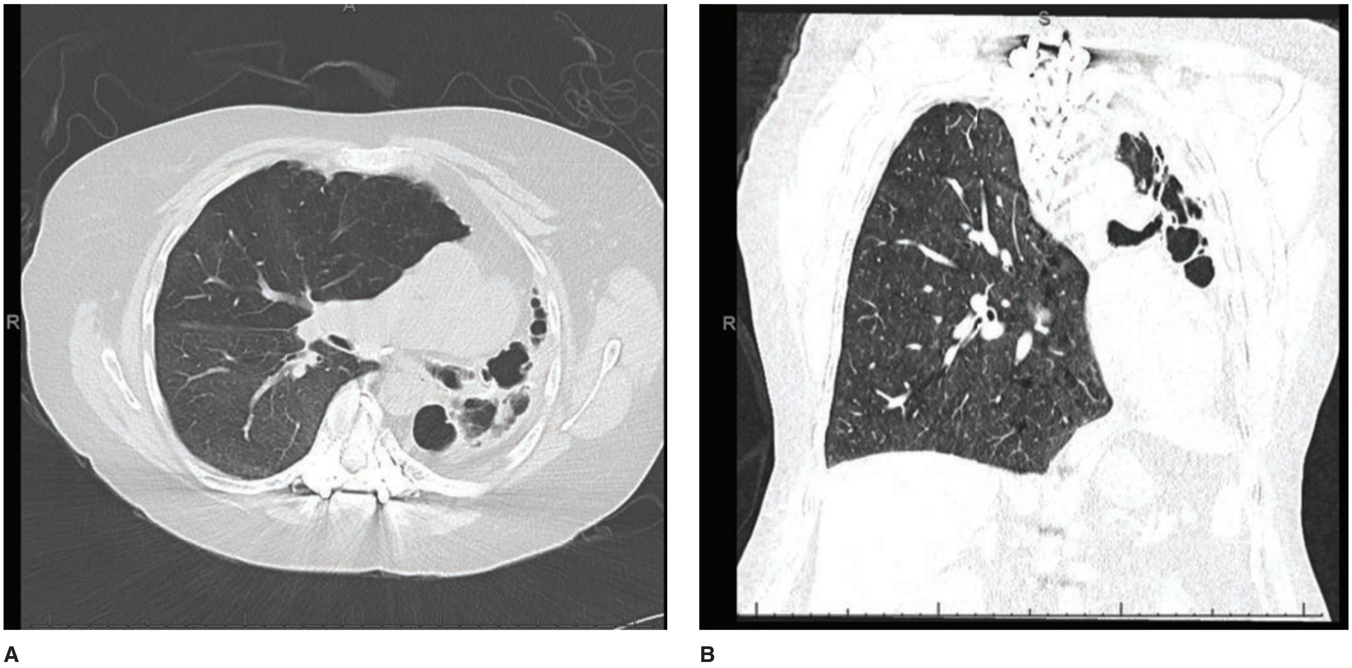

Figure 105-16 Left pulmonary hypoplasia. (**A**) Axial and (**B**) coronal reformatted CT lung images show marked volume loss with cystic bronchiectasis in the hypoplastic left lung, hyperexpanded right lung, and mediastinal shift to the left.

mesoderm during lung development is hypothesized as a possible etiology.[131] The nodules that follow are extremely slow growing and often cavitate into cystic structures exceeding 1 cm in size.[132] Due to its indolent nature, most cases are diagnosed in adults; affected individuals present with chronic cough, hemoptysis, or pneumothorax or hemothorax due to rupture of large cysts.[133]

Chest imaging reveals multiple bilateral solid nodules and large cystic lesions often 1 to 10 cm in size. Occasionally, air–fluid level may be seen in the cysts due to rupture of the adjacent bronchial artery.[133] The lesions may be indistinguishable from CPAM, bronchopulmonary sequestration, lymphangiomyomatosis, and pleuropulmonary blastoma and other malignant lesions on imaging. For this reason, histologic assessment is required for diagnosis. Biopsy demonstrates normal respiratory epithelium surrounding the cysts with an underlying layer of primitive mesenchymal cells with dark nuclei. Immunostaining may demonstrate positivity for vimentin, CD-56, and CD-10 but these findings are nonspecific.[133] The differentiating feature compared with other disorders is the low mitotic activity of the cells. In rare instances malignant transformation to rhabdomyosarcoma may be observed, highlighting the importance of histologic diagnosis.[134]

Due to the rare occurrence of this disease, no clear treatment guidelines exist. In asymptomatic cases, close monitoring with serial CT imaging to assess for enlargement of nodules and cysts is appropriate. Patients presenting with recurrent infection, hemothorax, hemoptysis, or pneumothorax should be treated with surgical excision of the culprit lesion.

VASCULAR DISORDERS

Described below are three developmental abnormalities of the pulmonary circulation: pulmonary artery sling and tracheal stenosis, unilateral pulmonary artery, and scimitar syndrome.

■ Pulmonary Artery Sling and Tracheal Stenosis

In rare instances, the left main pulmonary artery (PA) may originate from the right main PA instead of the pulmonary trunk. In order to reach the left lung, the left PA traverses between the trachea and esophagus, leading to a sling formation, hence the term *pulmonary artery sling* (PAS).[135] Left PAS can lead to posterior compression of the trachea, but the most common cause for severe symptoms is the presence of tracheal stenosis due to complete tracheal rings in up to 80% of patients with PAS.[136]

Two anatomic variants of PAS have been identified.[137] Type I left PAS is located immediately above the carina and compresses the right main bronchus and distal trachea leading to tracheobronchomalacia with resultant hyperinflation of the right lung. It is often associated with a tracheal bronchus, but tracheobronchial anatomy is otherwise normal.[138] In type II PAS, the sling is located more inferiorly (at the level of T5–T6) adjacent to an abnormally low horizontal carina and the presence of a bridging right bronchus. Type 2 PAS is subdivided into types IIA and IIB. In type IIA, there is a tracheal bronchus at the usual site of the carina that supplies the RUL; a bridging bronchus originating from the left main bronchus supplies the right middle and lower lobes. Type IIB is characterized by absence of the right upper lobe bronchus, with the right lung being supplied exclusively by the bridging bronchus. Both type II variants are strongly associated with long-segment tracheal stenosis. Other abnormalities occasionally encountered include right-sided pulmonary hypoplasia, scimitar syndrome, and foregut abnormalities.[139]

A chest radiograph may demonstrate prominent pulmonary vasculature with normal lung parenchyma in type I PAS. Posteroanterior and lateral views of the chest may show a distal T-shaped carina with difficult-to-visualize proximal trachea and atelectasis of the right lower lobe in type II left PAS.[135] In type II PAS, chest CT or MRI with angiography are excellent diagnostic tests to identify the anatomic type of PAS and length of tracheal stenosis (Fig. 105-17).[140] Three-dimensional reformatting of CT and MRI and virtual bronchoscopy can assist in surgical planning, especially for long-segment tracheal stenosis.[141,142]

Asymptomatic patients with type 1 left PAS can be monitored without intervention.[143,144] For those with respiratory symptoms, type 1 left PAS can be surgically corrected by reimplanting the left main PA into the pulmonary artery trunk anterior to the trachea. Surgical correction is often required for type II defects due to the presence of symptomatic tracheal stenosis. This most commonly involves a technique known as slide tracheoplasty in which the stenotic segment is transected at the midpoint, vertical incisions are

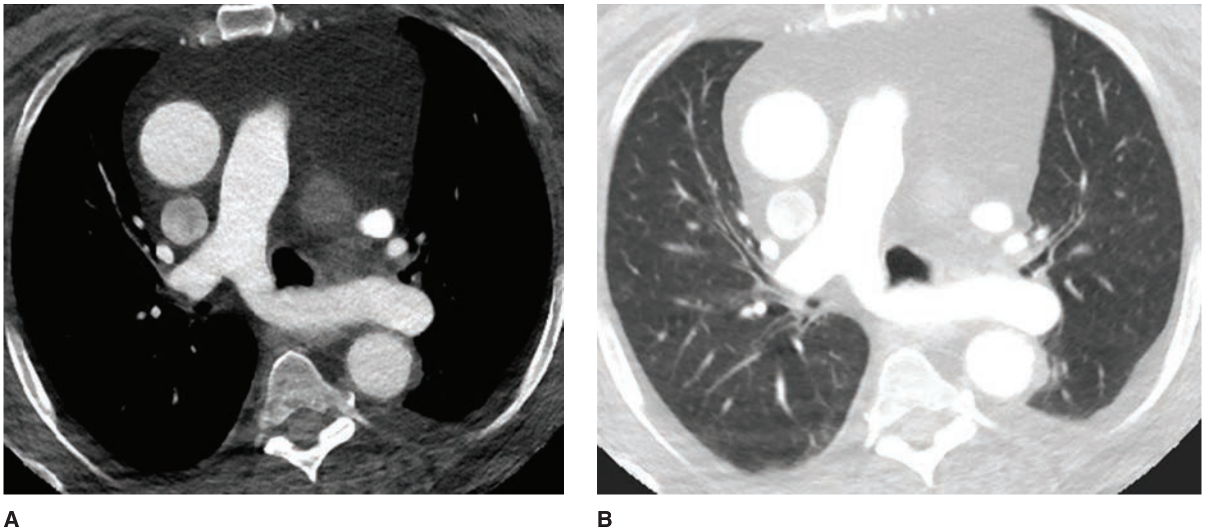

Figure 105-17 Pulmonary artery sling. Chest CT angiography images in mediastinal (**A**) and lung (**B**) window settings show an abnormal left pulmonary artery that arises from the right pulmonary artery and courses posterior to the distal trachea (just above the carina) and anterior to the esophagus. Note stretched and narrowed right upper lobe bronchus (**B**).

made in the proximal and distal narrowed segments on opposite anterior and posterior surfaces to expand them, and the two segments are slid together and sutured.

■ Unilateral Absent Pulmonary Artery

Unilateral absent pulmonary artery (UAPA) is a rare disorder with an estimated prevalence of 1 in 200,000 adults.[145] The pulmonary trunk and main pulmonary arteries arise from the sixth aortic arch, while the intrapulmonary vessels arise from the mesoderm surrounding the lung bud.[146] The involution of the ipsilateral proximal sixth aortic arch may result in UAPA with intrapulmonary vessels connecting directly to the distal sixth aortic arch and deriving blood supply from the systemic arteries. UAPA is invariably associated with a patent ductus arteriosus on the ipsilateral side with a left-to-right shunt.[147] Over time, multiple collaterals develop with bronchial, pleural, subclavian, and rarely coronary arteries.[148,149] The right pulmonary artery is absent in 60% of the cases. Absence of the left pulmonary artery is frequently associated with congenital cardiac abnormalities such as tetralogy of Fallot, coarctation of aorta, atrial septal defect, and right aortic arch.[150]

Up to 12% of patients may be asymptomatic, while 40% of patients may present with exertional dyspnea, 37% with recurrent lower respiratory tract infections, and 20% with hemoptysis.[151] Up to 44% of patients may develop pulmonary hypertension and may progress to Eisenmenger complex and right heart failure.[152]

Chest radiographs may demonstrate atrophic ipsilateral lung with elevated hemidiaphragm, hyperexpanded contralateral lung, and enlarged right heart border. CT of the chest with angiography is usually diagnostic, demonstrating an absent PA and ipsilateral atrophic lung (Fig. 105-18).[153] Bronchiectasis may also be present in cases where recurrent infection has occurred in the involved lung.[154] The peripheral pulmonary circulation in the affected lung remains intact with extensive systemic collateral blood supply. Cineangiography and MR angiography also can be used for diagnosis and are often used for preoperative assessment.

Management of UAPA depends on the severity of symptoms and complications. In cases with severe pulmonary hypertension, a trial of vasodilator therapy may be attempted as chronic high pressure in the contralateral PA and extensive systemic circulation may lead to pulmonary vascular remodeling similar to group I pulmonary arterial hypertension.[155] If identified at an early age, surgical revascularization with an aortopulmonary shunt, transposition of the interrupted pulmonary artery to the pulmonary trunk, or a modified Blalock-Taussig shunt may be performed.[146] Revascularization is not feasible in adulthood due to vascular remodeling in the contralateral lung. Patients are advised against travel to high altitudes, as they are at increased risk of high-altitude pulmonary edema (HAPE) in the hyperperfused contralateral lung.[156] Life-threatening hemoptysis may require embolization of the bleeding collateral artery. Lobectomy or pneumonectomy may be required for recurrent hemoptysis or necrotizing pulmonary infections.[157]

■ Scimitar Syndrome (Pulmonary Venolobar Syndrome)

Scimitar syndrome, also known as pulmonary venolobar syndrome, is a rare congenital disorder of the lung and pulmonary vasculature characterized by partial or total anomalous pulmonary venous return of the right lung (commonly the right lower lobe) to the inferior vena cava.[158] The anomalous pulmonary vein appears as a curvilinear shadow along the right heart border on a chest radiograph and resembles a Persian curved sword known as scimitar—hence the term scimitar syndrome.[159] It has a prevalence of 1 to 3 cases per 100,000 live births and female predominance (male:female ratio of 1:2).[160] It is frequently associated with right pulmonary hypoplasia, systemic arterial blood supply of the right lung, and congenital heart disease.[161,162] Scimitar syndrome represents only 5% of all partial anomalous pulmonary venous return abnormalities.[163]

During early embryogenesis, the pulmonary venous blood drains into the splanchnic venous circulation. Once the cardiac structures begin to develop, the pulmonary venous drainage transitions to cardiac drainage into the left atrium with regression of the systemic connection. Initially, both lungs drain into the left atrium via a common pulmonary vein, but this later divides into four separate pulmonary venous ostia in the left atrium. A defect during the transition from splanchnic drainage to cardiac drainage may lead to a total or partial anomalous pulmonary venous return of the right lung leading to scimitar syndrome.[164]

When the degree of pulmonary to systemic shunting is severe, patients may present in infancy or early childhood with tachypnea, pulmonary hypertension, and evidence of right heart failure.[165] With lesser degrees of shunting, patients may be asymptomatic or present

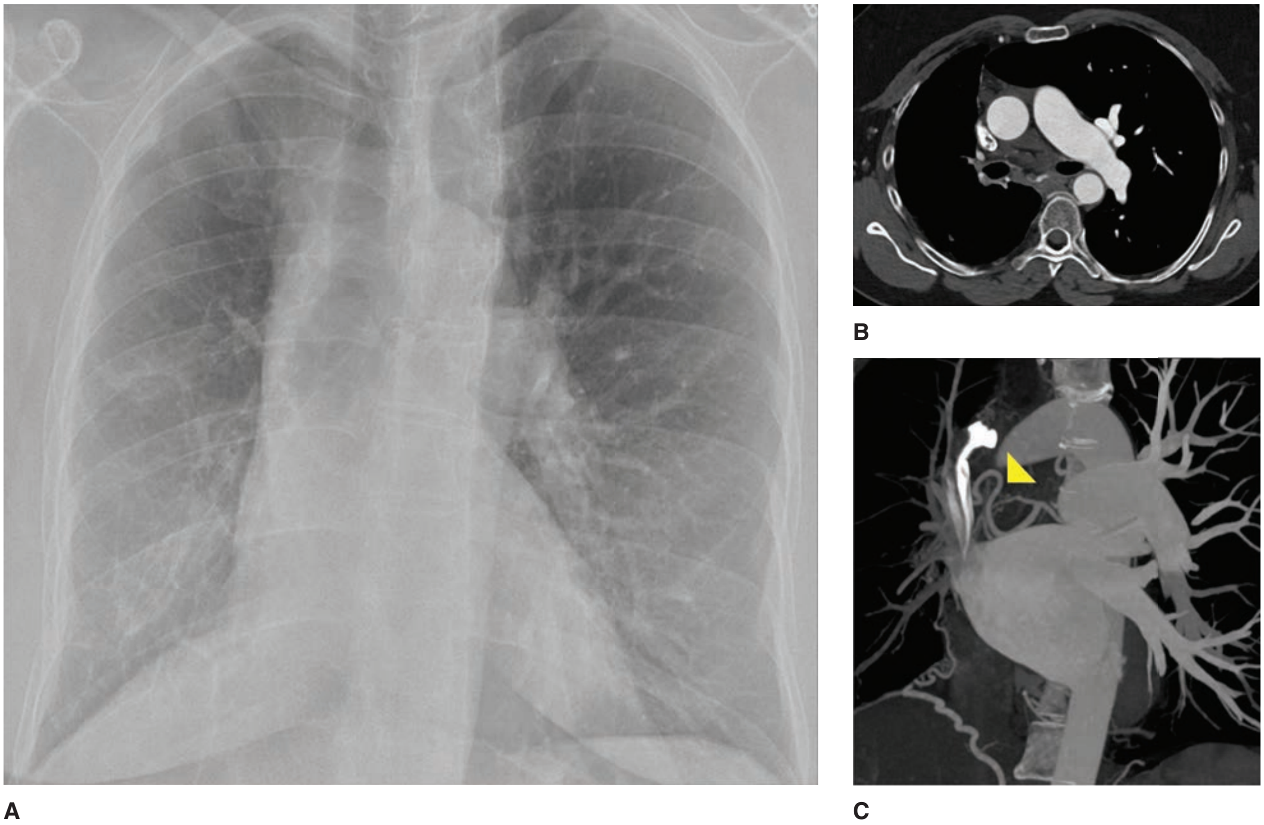

Figure 105-18 Absent right pulmonary artery. (**A**) Chest radiograph shows hypoplastic right lung. (**B**) Contrast-enhanced chest CT axial image shows absence of right pulmonary artery with normal main pulmonary trunk and left pulmonary artery. (**C**) Coronal maximum-intensity projection CT image shows multiple dilated bronchial and systemic collateral arteries supplying the right lung *(arrowhead)*.

in early adulthood with recurrent pneumonia (31%), dyspnea on exertion (19%), or hemoptysis (6%).

Chest radiographs may show the classic curvilinear right-sided opacity with right lung hypoplasia and ipsilateral mediastinal shift (Fig. 105-19). Two-dimensional transthoracic echocardiography (TTE) can be used to assess right ventricular function and estimated pulmonary artery pressure. In the suprasternal short-axis view with use of color Doppler, the left pulmonary vein can be seen entering the left atrium but not the right pulmonary vein. The parasternal short-axis view on TTE may demonstrate a small right main PA compared with normal-sized left PA. These findings can be confirmed on transesophageal echocardiogram. Lung scintigraphy with technetium-99m-labeled macroaggregated albumin can demonstrate the magnitude of blood flow to the right lung. Chest CT can accurately identify the systemic arterial supply of the affected lobe, anomalous pulmonary venous return, and site of venous drainage (infradiaphragmatic, hepatic veins, or supradiaphragmatic) (Fig. 105-20). More recently, MRI using isotropic flow-sensitive four-dimensional phase-contrast vastly undersampled isotropic projection reconstruction (PC-VIPR) has been used not only to identify anomalous pulmonary veins and cardiac morphology but also to analyze quantitated flow patterns and parameters including pulmonary-to-systemic shunt ratio without the need for angiography.[166]

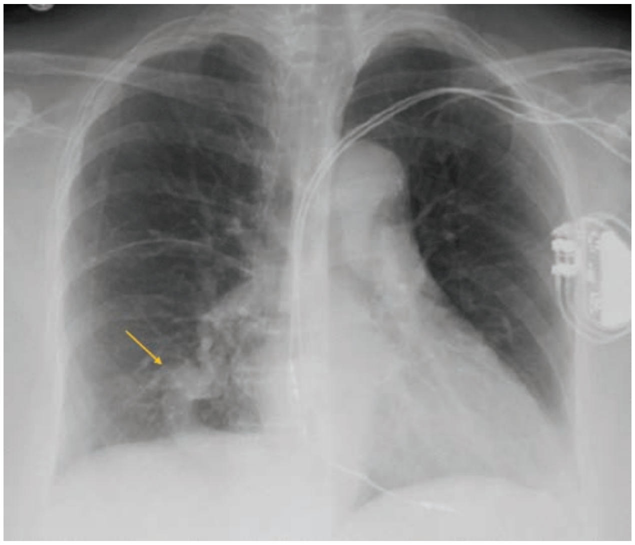

Figure 105-19 Scimitar syndrome. Chest radiograph reveals a curvilinear tubular opacity in the right lower hemithorax *(arrow)* that courses from the right hilum toward the IVC.

Management of scimitar syndrome depends on the severity of pulmonary to systemic shunting and its hemodynamic impact. Most often, the left-to-right shunt fraction decreases with age. For those with small shunt fractions and minimal symptoms, conservative management with follow-up echocardiography is recommended, and life expectancy is normal.[161] Surgical intervention is performed mainly to address a large shunt with right ventricular volume overload and pulmonary hypertension. The traditional surgical approach involves direct anastomosis of the anomalous pulmonary vein to the left atrium;[167] however, this has been associated with frequent thrombosis or stenosis of the anastomotic site.[160,161] A novel technique involves anastomosis of the anomalous pulmonary vein to a Gore-Tex vascular graft that is placed through the right atrial wall and sutured into a surgically created atrial septal defect to direct blood flow into the left atrium.[168]

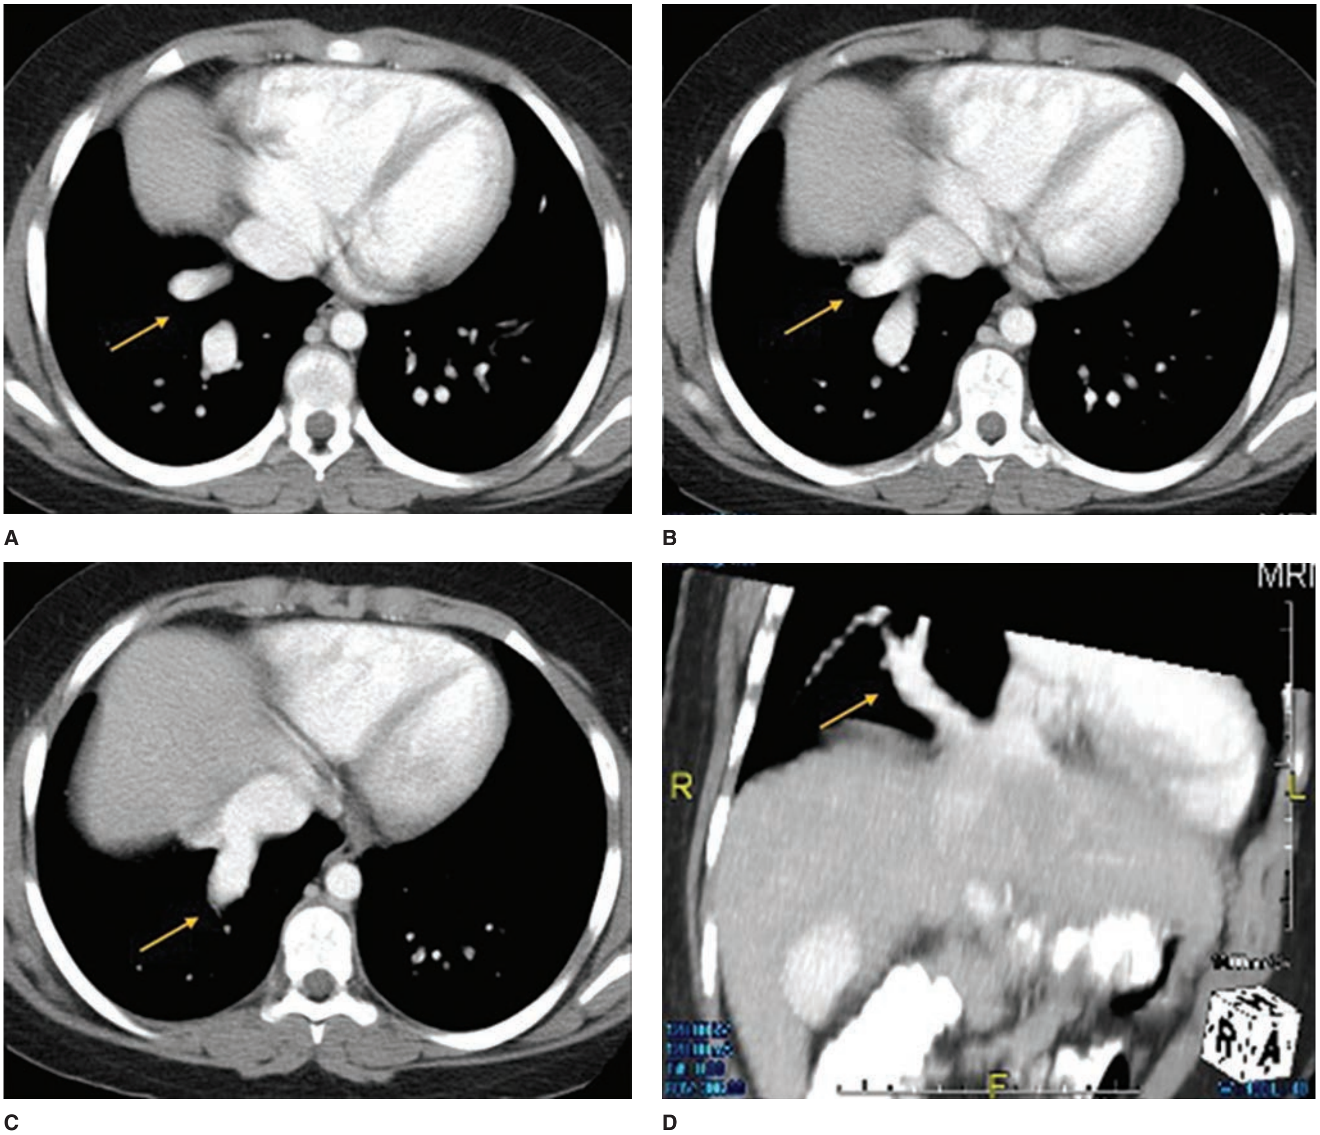

Figure 105-20 Scimitar syndrome (same patient as Fig. 105-19). Contrast-enhanced CT chest with serial axial images (**A–C**) and a coronal reformatted image (**D**) through the lower chest reveal an enhancing vascular structure in the right lower lobe that drains into the inferior vena cava and represents the anomalous draining right inferior pulmonary vein *(arrows)*.

CHAPTER 106

Lung Transplantation

Ramsey R. Hachem

INTRODUCTION

Lung transplantation is the ultimate treatment for patients with advanced and end-stage lung diseases. The number of lung transplants performed annually has grown consistently over the past 30 years worldwide.[1] Indeed, more than 4500 lung transplants have been reported annually to the International Thoracic Organ Transplant Registry of the International Society for Heart and Lung Transplantation (ISHLT).[1] Although donor organ availability is the primary barrier to increasing the volume of procedures performed, advances in donor selection, management, and the use of donation after circulatory death (DCD) donors and ex vivo lung perfusion (EVLP) have expanded the donor pool and allowed growth in transplant volumes worldwide.[2–7] Similarly, growing experience with lung transplantation has resulted in expansion in candidate selection. Today, lung transplant recipients are generally older, have more severe lung disease, have more comorbidities, and are more likely to be hospitalized or require life support before transplantation than 10 years ago.[2] Nonetheless, long-term survival after transplantation continues to improve compared with previous eras although the magnitude of this improvement is small on a year-to-year basis.[1,2] Indeed, long-term survival after lung transplantation remains significantly worse than after other solid organ transplants including kidney, liver, and heart transplantation.[2,8–10] Chronic lung allograft dysfunction (CLAD) has emerged as the leading obstacle to better long-term survival and the most common cause of death beyond the first year after transplantation.[1] The incidence of CLAD approaches 30% 3 years after transplantation, and the clinical course is characterized by a progressive decline in lung function culminating in severe clinical and physiologic impairment, respiratory failure, and death.[11–13] Other important complications after lung transplantation include infections, cardiovascular disease, chronic kidney disease (CKD), and malignancy.[1] Combined with episodes of rejection and the development of CLAD, these comorbidities adversely impact both quality of life and survival after lung transplantation. Better strategies and immunosuppressive regimens to prevent the development of CLAD and minimize the development of other complications are needed to improve long-term outcomes after lung transplantation. These have been the focus of basic, translational, and clinical studies, and ongoing research is critical to this mission.

HISTORY

The first human lung transplant was performed in 1963 by Dr. James Hardy at the University of Mississippi.[14] The recipient was a debilitated man with emphysema and lung cancer obstructing the left mainstem bronchus; other comorbidities included malnutrition and CKD. It was thought that a patient with a "terminal" condition was most appropriate for the first human lung transplant, which was considered an experimental treatment at the time. The patient underwent a left single lung transplant from a DCD donor. Immunosuppression consisted of mediastinal irradiation and azathioprine. The allograft functioned well with improvement in gas exchange; however, the recipient developed progressive kidney failure and ultimately died on day 18 after transplantation. In spite of the poor outcome, this early experience demonstrated that lung transplantation was technically feasible in humans, that the allograft could be physiologically functional, and that rejection could be averted at least for a brief period with the immunosuppression available at the time.

Enthusiasm for lung transplantation quickly waned after this promising but disappointing initial experience. Between 1963 and 1974, 36 lung transplants were reported.[15] The indications for transplantation spanned the spectrum of chronic lung diseases, and many recipients were moribund at the time of transplantation. Pneumonia, rejection, respiratory failure, and airway anastomotic complications were common causes of death.[15] One patient survived 6 months, and another survived 10 months after transplantation, but there were no long-term survivors. Consequently, there was a moratorium on lung transplantation although kidney, liver, and heart transplantation continued to develop clinically. The development of combined heart–lung transplantation was a key step in the progress toward successful isolated lung transplantation. After developing extensive surgical experience with primates in the laboratory, Dr. Bruce Reitz and a team of surgeons at Stanford University performed the first combined heart–lung transplant in a woman with idiopathic pulmonary arterial hypertension (IPAH).[16] The use of cyclosporin A was considered a critical component for this success, as it reduced the risk of rejection and minimized the required dose of steroids thereby promoting anastomotic healing. Initially, combined heart–lung transplantation was performed exclusively for patients with pulmonary vascular disease.[17] However, with growing experience and success, the procedure was then performed for patients with isolated lung disease, and the primary recipient's heart could be transplanted into a secondary recipient with isolated heart disease, a so-called domino heart transplant.[18,19] Lung rejection, obliterative bronchiolitis (OB), and pulmonary infections were common problems among survivors and presaged future clinical challenges in isolated lung transplantation.[17,20]

The first truly successful isolated lung transplant was performed by the Toronto Lung Transplant Group in 1983.[21] The group reported their experience with the first 2 single lung transplant recipients in 1986, both of whom were alive and well 26 and 14 months after transplantation.[21] This experience heralded the onset of the modern era of lung transplantation. The same group later reported their experience with en bloc double lung transplantation with a tracheal anastomosis in patients with bronchiectasis and emphysema.[22] However, this operation was associated with ischemic airway complications at the tracheal anastomosis and required prolonged cardiopulmonary bypass. Consequently, the operation was modified to sequentially transplant both lungs with the anastomoses at the level of the mainstem bronchi.[23] This is the currently performed surgery for bilateral lung transplants. Over time, more and more lung transplant programs were started across the world, and by 1993, more than 1000 lung transplants were reported to the ISHLT Registry.[1] Since then, transplant volumes have increased worldwide, and in 2017, more than 4500 lung transplant procedures were performed in adult and pediatric recipients.[24] In recent years, approximately 75% to 80% of all transplants are bilateral and only 20% to 25% are single lung transplants.[24]

INDICATIONS FOR LUNG TRANSPLANTATION

Lung transplantation has been performed for all benign lung diseases that progress to end stage and result in chronic respiratory failure. The most common indications for lung transplantation include chronic obstructive pulmonary disease (COPD), interstitial lung disease (ILD) from a variety of underlying causes, cystic fibrosis (CF), and pulmonary vascular disease.[1] Other benign lung diseases that are less common or less commonly progress to end stage also have been indications for lung transplantation including sarcoidosis, Langerhans cell histiocytosis (LCH), lymphangioleiomyomatosis (LAM), idiopathic bronchiectasis, and idiopathic OB. Retransplantation after graft failure has been an infrequent indication since the earliest era of lung transplantation. The most common indication for lung transplantation has changed over time. In 2000, almost 50% of all transplants reported to the ISHLT registry were performed for COPD and emphysema due to α1-antitrypsin deficiency, whereas 16% were performed for CF and 17% were performed for ILD.[24] In contrast, in 2017, only 29% of all transplants were performed for COPD and emphysema due to α1-antitrypsin deficiency, and 13% were performed for CF, while 40% were performed for ILD.[24] In the United States, this pattern is more striking. In 2018, 60% of lung transplants were performed for ILD, approximately 24% were performed for COPD, 10% for CF and other bronchiectasis, and 6% for pulmonary vascular disease.[2]

Reasons for differences in indications for transplantation in different countries are complex and include variations in clinical practice, social norms, and donor organ allocation policies. In the United States, donor lungs are allocated based on the lung allocation score (LAS), which is meant to maximize transplant benefit by accounting for risk of death on the waiting list and likelihood of survival in the first year after transplantation.[25,26] Early after implementation of the LAS, the distribution of underlying diagnoses undergoing transplantation changed significantly, favoring those with ILD, and this trend has continued over time.[2,27] The Eurotransplant International Foundation, the organization responsible for organ allocation in multiple European countries, also uses the LAS to allocate donor lungs.[28] Other countries and regions including France, Canada, the United Kingdom, and Scandinavia use different methods to allocate donor lungs and account for candidate urgency.[29–31] These systems have allowed high-urgency patients who are often critically ill to undergo transplantation.

RECIPIENT SELECTION

Identifying patients most likely to benefit from transplantation is critical because donor lungs are scarce resources and transplantation is a complex treatment with significant risks. Guidelines for recipient selection have been developed by the ISHLT.[32] In general, the ideal candidate has severe lung disease with ineffective medical therapy and a limited life expectancy yet is ambulatory and does not have significant medical or psychosocial contraindications. Transplantation should be considered if there is a high risk of death within 2 years and there is a high likelihood of survival 5 years after transplantation.[32] Clearly, making these assessments can be challenging in many cases. Furthermore, assessing the potential impact of pre-existing comorbidities on posttransplant outcomes can be very difficult. Not surprisingly, selection criteria for listing and transplantation vary among centers and countries, with some centers accepting and transplanting patients with comorbidities that other centers consider absolute contraindications. Nonetheless, comorbidities have historically been categorized as relative or absolute contraindications, and considering the overall sum of relative contraindications is critical when multiple comorbidities are present.

Comorbidities identified by the ISHLT guidelines as absolute contraindications are listed in Table 106-1.[32] However, the guidelines are not intended to be proscriptive, and some comorbidities listed as absolute contraindications are characterized using verbiage that allows clinicians and centers sufficient latitude to make individualized decisions regarding a patient's candidacy for transplantation. Among patients with a history of cancer, the risk of recurrence affects the appropriateness and timing of lung transplantation. In general, a 5-year cancer-free interval is recommended for most malignancies. However, a 2-year cancer-free interval may be appropriate with certain low-risk cancers such as prostate cancer. A large ISHLT registry study examined the impact of pretransplant cancer on outcomes after heart and lung transplantation.[33] The diagnosis of cancer before lung transplantation did not impact survival after transplantation, and no specific cancer was associated with an increased mortality after lung transplantation.[33] However, patients with leukemia, lymphoma, or myeloma had significantly worse survival after heart transplantation.[33] These findings suggest that the current approach to candidate selection for patients with cancer before lung transplantation are appropriate. Nonetheless, these may be overly conservative in some circumstances, and centers make individualized decisions in these cases. Indeed, a single-center series reported good short-term survival without a cancer-free period in some patients with prostate cancer before lung transplantation.[34]

TABLE 106-1 Absolute Contraindications to Lung Transplantation

Cancer
Acute renal failure with low likelihood of recovery
Chronic kidney disease with glomerular filtration rate <40 mL/min/1.73 m^2
Cirrhosis with portal hypertension
Acute coronary syndrome or stroke within 30 days
Septic shock
Active extrapulmonary or disseminated infection
Active tuberculosis infection
HIV infection with detectable viral load
Progressive cognitive impairment
Nonadherence to medical therapy
Uncontrolled psychiatric illness
Lack of a reliable and adequate social support system
Severely impaired functional status with limited rehabilitation potential
Substance abuse or dependence
Active tobacco smoking

Significant dysfunction of other vital organs, including chronic kidney disease (CKD), liver disease, or heart disease is generally considered a contraindication. Progressive acute renal failure, liver failure, and recent acute coronary syndrome or stroke also are considered contraindications. Similarly, chronic infection with highly virulent or resistant organisms can be a contraindication to transplantation at some centers, but this is not a uniform practice, and many patients with chronic infection with multidrug-resistant or pan-resistant *Pseudomonas aeruginosa* are suitable candidates for transplantation and have good long-term outcomes.[35,36] In contrast, chronic infection with certain genomovars of *Burkholderia cepacia* complex or *Mycobacterium abscessus* is associated with adverse clinical outcomes after transplantation.[37–40] Consequently, many transplant programs consider these infections absolute contraindications to transplantation. Historically, an unstable clinical condition was considered an absolute contraindication to transplantation at most centers. However, in the United States, approximately 15% of lung transplant recipients are in an intensive care unit at the time of transplantation, and 8% to 10% require either invasive mechanical ventilation or extracorporeal membrane oxygenation (ECMO) support.[2] Indeed, the use of ECMO as a bridge to transplantation has increased worldwide over the past 10 years with acceptable long-term survival among those who are successfully bridged to transplant.[41–43] During the coronavirus disease 2019 (COVID-19) pandemic, ECMO has been used as a bridge to recovery in patients with very severe acute respiratory distress syndrome (ARDS), and a minority who would not recover have gone on to lung transplantation.[44,45] Lastly, active tobacco use, drug or alcohol dependence, nonadherence to medical therapy, uncontrolled psychiatric illness,

TABLE 106-2 Relative Contraindications to Lung Transplantation

Advanced age
Obesity with a BMI >35 kg/m^2
Severe malnutrition with a BMI <16 kg/m^2
Severe esophageal disease (e.g., esophageal dysmotility, gastroesophageal reflux)
Extensive previous thoracic surgery or pleurodesis
Severe osteoporosis
Chronic pulmonary infection with highly virulent organisms (e.g., *Mycobacterium abscessus abscessus*, *Lomentospora prolificans*, *Burkholderia cepacia* complex)
Hematologic disorders
Thoracic cage deformity that may be expected to cause severe restrictive ventilatory defect after transplant

and lack of adequate social support are considered absolute contraindications to transplantation for obvious reasons.

Relative contraindications to transplantation are listed in Table 106-2. In the earliest era of lung transplantation, age by itself was considered an important factor in candidate selection; however, over time, it was recognized that comorbidities associated with advanced age were more important than age alone. Indeed, in the United States, patients 65 years old and older have had the greatest increase in transplant volume over the past 10 years and accounted for 38.6% of all lung transplant recipients in 2020.[2,46] Likewise, hepatitis C virus (HCV) infection was previously considered a relative contraindication, but the advent of highly effective direct-acting antiviral (DAA) therapy can achieve sustained virologic response either before or after lung transplantation, making transplantation feasible with outcomes similar to those in uninfected patients.[47] Successful lung transplantation has been reported in patients infected with human immunodeficiency virus (HIV), but this is currently reserved to centers with extensive experience in both lung transplantation and HIV care.[48,49]

TIMING OF TRANSPLANTATION

For patients with progressive or advanced lung disease, early referral for transplant evaluation is ideal. The evaluation is comprehensive and often identifies comorbidities that require intervention to improve the patient's candidacy and facilitate the postoperative recovery. For example, occult coronary artery disease may be uncovered during the evaluation, and percutaneous revascularization may be necessary. Furthermore, many patients and their families face significant psychosocial stressors with transplantation including personal finances, identifying a caregiver, the logistics of moving closer to the transplant center, and the psychological trauma associated with disability and major surgery. Thus, early referral provides an opportunity for patients to better prepare for transplantation and the necessary education about the transplant process and life after transplantation. In addition, outcomes after transplantation are influenced by the patient's clinical condition immediately before transplantation, and referral before the patient becomes critically ill and transplantation becomes emergent probably improves posttransplant outcomes.

Interstitial Lung Diseases

There is often a delay in the diagnosis of interstitial lung diseases (ILD).[50] Moreover, the clinical course is typically progressive and sometimes unpredictable. This is particularly true in idiopathic pulmonary fibrosis (IPF), which is the most common ILD leading to transplantation. Furthermore, the prognosis of patients with IPF is poor in spite of available medical therapy.[51,52] Indeed, mortality on the waiting list for transplantation is highest for patients with ILD.[2,32] In the latest Scientific Registry of Transplant Recipients (SRTR) annual report, waitlist mortality for patients with ILD was 29.7 deaths per 100 waitlist-years compared with 9.4 deaths per 100 waitlist-years for patients with COPD.[2] Consequently, early referral for transplantation is crucial. For patients with IPF, referral is recommended at the time of diagnosis.[32] For any form of pulmonary fibrosis, a decline in forced vital capacity ≥10% or diffusing capacity ≥15% in the past 2 years, and resting or exertional hypoxemia requiring supplemental oxygen, are other criteria for referral for transplantation.[32] General guidelines for listing for transplantation are outlined in Table 106-3.[32]

Chronic Obstructive Pulmonary Disease

COPD generally follows a slowly progressive clinical course, and short-term survival is preserved in spite of severe physiologic

TABLE 106-3 Guidelines for Listing for Lung Transplantation

Interstitial lung diseases
Decline in FVC >10% or >5% with radiographic progression in the past 6 months
Decline in D_{LCO} >10% in the past 6 months
Oxygen saturation <88% during a 6-min walk test
Decline in 6-min walk distance >50 meters in the past 6 months
Pulmonary hypertension
Hospitalization for a respiratory indication
Chronic obstructive pulmonary disease
BODE index ≥7
FEV_1 <20% predicted
Chronic hypercapnia
History of severe exacerbations
Moderate to severe pulmonary hypertension
Cystic fibrosis
FEV_1 <25% predicted
Hypoxemia (Pa_{O_2} <60 mm Hg)
Hypercapnia (Pa_{CO_2} >50 mm Hg)
An exacerbation requiring mechanical ventilation
Need for noninvasive mechanical ventilation
Pulmonary hypertension
Frequent exacerbations requiring hospitalization
Recurrent massive hemoptysis despite bronchial artery embolization
Rapid decline in lung function
World Health Organization functional class IV
Pulmonary hypertension
ESC/ERS high risk or REVEAL risk score >10 despite aggressive therapy
Progressive hypoxemia
Progressive kidney or liver dysfunction due to pulmonary hypertension
Development of hemoptysis

FVC, forced vital capacity; D_{LCO}, diffusing capacity for carbon monoxide; FEV_1, forced expiratory volume in 1 s; ESC/ERS, European Society of Cardiology/European Respiratory Society; REVEAL, Registry to Evaluate Early and Long-term Pulmonary Arterial Hypertension Disease Management.

impairment relative to other end-stage lung diseases. In the SRTR annual report, waitlist mortality is lowest for patients with COPD.[2] The BODE (Body-mass index, degree of airflow Obstruction, Dyspnea, and Exercise capacity) index is a multidimensional composite score developed to predict survival in patients with COPD, and an increasing score correlates well with survival.[53] For example, a BODE index of 7 to 10 is associated with a mortality of 80% at 52 months.[53] Some have advocated using of the BODE index to estimate or predict the survival benefit of transplantation in patients with severe COPD.[54] However, it is noteworthy that the BODE index was calculated with an older cohort of patients, and some were still smoking. These differences from patients who are being considered for transplantation raise the possibility that the BODE index may underestimate predicted survival in this cohort.[55] Nevertheless, a BODE index of 5 or 6 with frequent exacerbations, an increase in the BODE index >1 over 24 months, or a forced expiratory volume in 1 s (FEV_1) <25% are general criteria for referral for transplantation.[32] Other criteria for referral include progressive disease in spite of optimal medical therapy, supplemental oxygen, and pulmonary rehabilitation; and unacceptably poor quality of life.[32] Guidelines for listing for transplantation are outlined in Table 106-3.

Cystic Fibrosis

CF is caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene. CFTR modulators improve production, intracellular processing, or function of the defective CFTR protein. These have revolutionized the care of patients with CF by targeting the underlying genetic basis of the disease rather than treating the downstream effects. The combination of elexacaftor-tezacaftor-ivacaftor improves lung function, decreases the frequency of exacerbations, and improves quality of life in patients with one or more copies of the Phe508del mutation, which is the most common CF mutation.[56] The full impact of elexacaftor-tezacaftor-ivacaftor on transplantation remains to be seen. However, it should be noted that there are many patients with CF who developed advanced lung disease before the availability of highly effective modulators, and although treatment may postpone the need for transplantation, it is likely that these patients will ultimately require transplantation. Therefore, the Cystic Fibrosis Foundation recommends early referral for transplantation to optimize patients medically, psychosocially, and financially.[57] Indeed, late referral for transplantation is associated with an increased risk of waitlist mortality.[58] An FEV_1 <50% predicted associated with a 20% relative decline within the previous 12 months, or an FEV_1 <40% predicted with markers of shortened survival (reduced 6-min walk distance, hypoxemia, hypercapnia, pulmonary hypertension, low body mass index, frequent exacerbations, massive hemoptysis, or pneumothorax), or an FEV_1 <30% predicted are criteria for referral for transplantation.[57] Guidelines for listing for transplantation are outlined in Table 106-3.

Pulmonary Hypertension

Over the past 30 years, pulmonary vasodilators have revolutionized the care of patients with pulmonary hypertension. The decisions to refer and to list a patient for transplantation are difficult in this patient population. Suspected or known causes of pulmonary hypertension that are generally poorly responsive to medical therapy such as pulmonary veno-occlusive disease and pulmonary capillary hemangiomatosis are indications for early referral for transplantation. In other patients with pulmonary hypertension, use of the European Society of Cardiology/European Respiratory Society (ESC/ERS) and the Registry to Evaluate Early and Long-term Pulmonary Arterial Hypertension Disease Management (REVEAL) models to risk stratify patients is recommended.[32,59,60] Patients who cannot achieve a low risk status within 6 months of aggressive therapy should be referred for transplant evaluation.[32,59,60] Guidelines for listing for transplantation are outlined in Table 106-3.[32]

DONORS

Worldwide, the vast majority of lung donors are deceased. Living donor lobar lung transplantation is an operation in which two people donate their lower lobes to one recipient. This operation was popularized in the mid-1990s and was feasible for adolescent or small-statured adult recipients who could gain sufficient lung function and fill their thoracic cavity with a right and a left lower lobe from two donors. However, by the mid-2000s, this operation fell out of favor in the United States although it remains a common lung transplant surgery in Japan.[61] Most deceased donors are brain-dead, but non–heart beating donors, or DCD donors, account for a growing proportion of donors in many parts of the world including Europe and Australia.[62] In the United States, DCD donors accounted for 4.8% of all lung donors in 2018.[2] Lungs are recovered from approximately 20% of all deceased organ donors because they are more susceptible to injury related to brain death, aspiration, and ventilator-induced lung injury. In fact, in the United States, there were 2577 lung donors in 2020 compared with 3761 heart donors, 9702 (9211 deceased and 491 living) liver donors, and 17,162 (11,925 deceased and 5237 living) kidney donors.[63]

Donor Selection

The original criteria for donor selection were derived from expert opinion and experience rather than studies to identify variables associated with clinical outcomes. Not surprisingly, these early criteria were fairly stringent and focused on minimizing risk rather than maximizing donor utilization. Indeed, in 1990, there were fewer than 500 people on the waiting list for lung transplantation in the United States, and the median waiting time was 217 days.[64] So, a conservative approach to donor selection was reasonable and expected at the time. However, it quickly became apparent that conservative donor selection criteria would not meet the rapidly growing demand as the number of people waiting for transplantation increased to nearly 3500 by 1999, and the median waiting time approached 2 years.[64] In 2003, an ISHLT consensus report defined an ideal lung donor as having the following characteristics: age <55 years, smoking history <20 pack-years, clear chest x-ray, absence of purulent secretions on bronchoscopy, absence of chest trauma, and a Pa_{O_2}:Fi_{O_2} ratio >300.[65] Furthermore, the group recognized the limitations of using such stringent and conservative criteria for donor selection and the benefits of expanding the donor pool with the use of marginal or extended-criteria donors.[65] There is no widely accepted definition for marginal or extended-criteria donors; these are generally defined as not meeting all of the criteria of an ideal donor. The term *marginal* is a misnomer as it implies inferior quality. However, multiple centers reported good outcomes after transplantation from extended-criteria donors as early as the mid 1990s.[66–68] Clearly, there is a balance between expanding the donor pool to meet the demand of the increasing number of patients on the waiting list and minimizing the risk of death while waiting and having good outcomes after transplantation. A number of lung donor scoring systems have been developed to make donor acceptance more objective.[69–72] These have generally predicted outcomes including donor acceptance and recipient survival reasonably well. However, an inherent limitation to the clinical use of a donor score to decide about donor acceptance is that the scoring systems do not account for recipient characteristics and their impact on outcomes. For example, a donor may be perfectly acceptable for a recipient at low risk for severe primary graft dysfunction (PGD) (e.g., a patient with COPD who does not have pulmonary hypertension), but the same donor may not be acceptable for a recipient at high risk for severe PGD (e.g., a patient with severe pulmonary hypertension or obesity). Interactions between donor and recipient factors are complex, and these have an important impact on outcomes. Future research in donor selection will need to account for recipient factors and these interactions to maximize the donor pool and improve outcomes.

Traditionally, only donors who were not infected with HCV were accepted for lung transplantation. However, the advent of highly effective DAA has made transplantation from hepatitis C viremic donors into uninfected recipients a clinical possibility.[73–75] Small case series have reported good short-term outcomes and early resolution of HCV infection among recipients who became viremic in the posttransplant period with DAA.[73–75] In one study, placing HCV-infected donor lungs on EVLP and irradiating the perfusate with ultraviolet C before transplantation reduced the viral load that would be transmitted to the recipient.[74] However, a recent study of HCV-infected heart donors identified an increased risk of acute cellular rejection (ACR) associated with hepatitis C viremia, but this has not been reported in lung transplantation.[76] The long-term impact of these early episodes of ACR on graft function and patient survival remains to be seen. Clearly, the use of HCV-infected lung donors will expand the donor pool, and highly effective DAA appears to prevent long-term infection in the recipient. Whether this will result in a higher incidence of ACR or other unexpected complications after lung transplantation remains to be seen as experience with this approach grows.

■ Donor Management

The donor's premortem clinical condition can result in lung injury due to brain injury, aspiration of gastric or oropharyngeal secretions, pneumonia, and mechanical ventilation. Additionally, aggressive fluid resuscitation can exacerbate this lung injury by increasing extravascular lung water. Careful donor management strategies aimed at maximizing lung donor utilization can be successful without adversely affecting other organ retrieval (e.g., kidney). Multiple studies of donor management protocols have been published.[77–79] These consistently show that relatively simple donor management protocols increase the number of donor lungs suitable for transplantation without adversely impacting clinical outcomes after transplantation. The main aspects of these protocols include recruitment maneuvers, careful attention to fluid balance, bronchoscopy to clear retained secretions, and techniques to prevent aspiration such as elevating the head of the bed and adequate inflation of the endotracheal tube balloon.[77–79] Lung-protective ventilation with low tidal volume mitigates the risk of ventilator-induced lung injury and other pulmonary complications in patients with and without acute respiratory distress syndrome (ARDS) and those undergoing abdominal surgery.[80–82] A randomized controlled trial demonstrated that lung-protective ventilation with a tidal volume of 6 to 8 mL/kg resulted in increased donor lung utilization.[5] More recently, prone ventilation for 12 h or longer to decrease atelectasis was shown to improve gas exchange and increase donor utilization.[83]

■ Ex Vivo Lung Perfusion

Traditionally, lungs are flushed with a cold low-potassium dextran solution antegrade and retrograde after they are explanted from the donor, then placed in a bag of cold preservation fluid on ice for transport to the recipient hospital.[84] This cold preservation strategy has been the standard approach to lung transplantation over the past 30 years. The purpose of cold preservation is to inhibit cellular metabolism through hypothermia and mitigate ischemia-reperfusion injury. However, in spite of optimal preservation, PGD remains a significant clinical problem after transplantation. More importantly, this static preservation does not permit serial assessment of the lungs once they have been retrieved from the donor. EVLP is a technique to perfuse and ventilate the lungs outside the donor's body that permits serial evaluation of lung function and may decrease pulmonary edema. EVLP was first used in clinical practice in 2006 in Lund, Sweden.[85] Lungs from 9 donors that were deemed unsuitable for transplantation were perfused ex vivo. Of these, 6 were "reconditioned" to acceptable function and were transplanted; 2 recipients died in the first year and 4 remained alive 2 years after transplantation.[85] In a subsequent landmark study, 4 h of EVLP improved gas exchange in 20 of 23 lungs from donors deemed at high risk for failure.[86] These lungs were transplanted, and recipients had outcomes similar to control patients who underwent transplantation using standard donor lungs.[86] Since that early experience, there have been numerous advances in EVLP, and multiple platforms and protocols are available in clinical practice.[87] EVLP can be portable, where donor lungs are placed on the device after they are explanted and perfused during transport to the recipient hospital. An alternative EVLP platform is static, where donor lungs are preserved in the standard fashion and transported on ice to be placed on EVLP at the recipient hospital.[87,88] Additional variabilities in platforms and protocols include the set flow, ventilation, and use of an acellular perfusate or the addition of erythrocytes to the perfusate. The optimal platform and protocol are not clear, and there have been no head-to-head comparisons of the different approaches. Instead, transplant programs have developed their local practices with a given EVLP platform. Nonetheless, EVLP has expanded the donor pool, and ongoing research is focused on reconditioning unsuitable lungs.[89]

LUNG TRANSPLANT SURGERY

Bilateral lung transplantation is currently the most commonly performed lung transplant surgery worldwide.[1] In 2017, 3727 bilateral lung transplants and 827 single lung transplants were reported to the ISHLT Registry.[24] Living donor lobar lung transplantation has not been performed in the United States since 2013 and is now mainly performed in countries with very limited access to deceased donor lungs.[61,63] Bilateral lung transplantation is associated with significantly better survival than single lung transplantation. In the ISHLT registry, bilateral lung transplantation had a median survival of 7.8 years whereas single lung transplantation had a median survival of 4.8 years.[24] However, it should be noted that patients in these cohorts were not randomized to receive a bilateral or a single lung transplant, and comorbidities that may have influenced the decision to perform a single lung transplant may also impact survival. Thus, it is unclear how much of the survival benefit seen with bilateral lung transplantation is due to the operation performed and how much is related to the underlying recipient characteristics. Single lung transplantation may expand the donor pool, but it provides less lung function and may not be appropriate with extended-criteria donors. No randomized controlled trial of bilateral versus single lung transplantation has ever been performed.

The underlying diagnosis leading to transplantation can impact the decision about a bilateral or a single lung transplant. Cystic fibrosis and other causes of bronchiectasis require a bilateral transplant to avoid spill-over infection from the remaining native lung into the allograft if a single lung transplant is performed. Otherwise, single lung transplantation can be performed for all other indications. However, pulmonary hypertension poses a unique physiologic scenario. Although single lung transplantation has been performed successfully in the past for pulmonary hypertension,[90,91] the allograft receives the majority of perfusion while ventilation is evenly distributed between the native lung and the allograft. This can result in severe ventilation–perfusion abnormalities when there are allograft complications such as PGD, acute rejection, or pneumonia. Therefore, bilateral lung transplantation is preferred for patients with pulmonary hypertension. Combined heart–lung transplantation is reserved for patients with Eisenmenger syndrome who have a congenital defect that is either uncorrectable or technically very difficult to repair in combination with lung transplantation.

What follows is a brief overview of the surgical approach to transplantation. Bilateral anterolateral thoracotomy is the most common incision during bilateral transplantation.[84] This incision can avoid dividing the sternum, or the sternum can be divided as in a clamshell incision to provide additional exposure if there is cardiomegaly or a small thoracic cavity. A median sternotomy is an alternative approach and is preferred by some surgeons. Either a posterolateral or an anterolateral thoracotomy can be performed during single lung transplantation, although the anterolateral approach generally provides better exposure to the hilum. The chest cavity is entered in the fourth intercostal space as the intercostal muscles are divided. The lung with the worst physiologic function is explanted first, as this may avoid the need for extracorporeal support (e.g., ECMO or cardiopulmonary bypass) during the transplant. Dissection of pleural adhesions can be difficult in patients with previous thoracic surgery, pleurodesis, or underlying bronchiectasis. Careful attention is made to protect the phrenic, vagus, and recurrent laryngeal nerves. The sequence of anastomoses is bronchial, arterial, then venous. The bronchial anastomosis is an end-to-end anastomosis. Similarly, the pulmonary arterial anastomosis is also an end-to-end anastomosis. The venous anastomosis is made by amputating the recipient's venous stumps to create an atrial cuff, which is then sutured to the donor atrial cuff.[84] Once hemostasis is confirmed, chest tubes are placed to drain the pleural spaces, and the chest is closed by reapproximating the sternum (if a sternotomy was done) and the ribs. Then, the muscle, fascia, and skin are reapproximated.

Approximately 30% to 50% of lung transplant surgeries require the use of cardiopulmonary bypass or ECMO support, although center and surgeon preferences are variable.[92,93] Historically, cardiopulmonary bypass was the standard platform for intraoperative support, but veno-arterial ECMO has gained popularity over the past 5 years. Indeed, observational studies suggest that ECMO is associated with less bleeding; a lower incidence of PGD; a shorter duration of mechanical ventilation, ICU stay, and hospital length of stay; and a lower incidence of renal failure.[93–95] The decision to use cardiopulmonary bypass or ECMO intraoperatively is based on severity of the underlying lung disease, the ability to support the patient with single lung ventilation and perfusion, and surgeon preferences. In general, patients with severe pulmonary hypertension and those with severe hypercapnic or hypoxemic respiratory failure require mechanical support. In addition, patients who become unstable hemodynamically during the operation require mechanical support.

MEDICAL MANAGEMENT

Early postoperative management and ongoing monitoring of the lung transplant patient are considered below.

Early Postoperative Management

Immediate postoperative care is focused on ventilatory support, hemodynamic management, analgesia, antibiotic prophylaxis, and immunosuppression. There have been no randomized controlled trials to guide early critical care practices, and clinical protocols vary across centers. Specifically, there have been no randomized controlled trials to guide ventilator management in the immediate period after transplantation, and although lung-protective ventilation is commonly used, tidal volumes are usually set based on recipient rather than donor ideal body weight even if there is a significant size discrepancy.[96,97] Transplanted lungs are susceptible to pulmonary edema because lymphatics are not re-anastomosed and PGD is common. Therefore, a negative fluid balance is favored as hemodynamics allow. Indeed, retrospective studies suggest that intraoperative fluids and a high central venous pressure are associated with an increased risk of PGD, prolonged duration of mechanical ventilation, and death.[98,99] Attempts to wean patients from mechanical ventilation are made as soon as practical. Pulmonary hygiene to clear secretions and avoid atelectasis is critical in the first few days after extubation. This is often complicated by incisional pain and the need for opiates, and thoracic epidural analgesia is an effective alternative.[100] The donor and the recipient are given empiric broad-spectrum antibiotics before the transplant, and these are continued for the first 1 to 2 weeks after transplant. The antibiotic regimen is typically adjusted based on culture results and sensitivity patterns. Prophylactic regimens against opportunistic infections are variable across centers. However, most centers implement prophylaxis in patients at risk for cytomegalovirus (CMV) (e.g., seropositive recipients or seronegative recipients of seropositive donors) with valganciclovir for the first year after transplantation.[101] Likewise, most centers use long-term prophylaxis against *Pneumocystis jiroveci*. Fungal prophylaxis is highly variable across centers, with some using universal prophylaxis against molds while others start antifungals based on culture results from bronchoscopy specimens.

Long-Term Monitoring

Long-term care after lung transplantation is complex. Patients are at risk of numerous complications including rejection, infections, and medication-associated adverse events. Furthermore, the immunosuppressive regimen has a narrow therapeutic window with significant risk of toxicity and complex drug–drug interactions. Therefore, transplant centers follow patients closely. Institutional protocols vary and depend on local resources and expertise as well as the distance of the patient's residence to the transplant center. In general, patients are seen frequently (e.g., weekly or biweekly) at the transplant center in the first 3 or 4 months after transplantation, and routine lab work including therapeutic drug monitoring is checked frequently during this period. The frequency of visits typically decreases after the first few months; at many centers, patients are seen monthly during the first year after transplantation and every 2 to 3 months thereafter. Collaboration and close communication between the transplant center and local referring physicians is essential if patients live at a distance from the transplant center. During these visits, patients are assessed for respiratory symptoms and signs and symptoms of medication side effects, and allograft function is monitored with pulmonary function tests. Home spirometry is an effective method of identifying complications early in between visits.[102,103] This has been particularly useful during the COVID-19 pandemic.

Acute cellular rejection (ACR) is a common complication early after transplantation and is often clinically silent. Bronchoscopy with transbronchial lung biopsies is the current gold standard for the diagnosis of ACR. Thus, many transplant programs use a surveillance bronchoscopy protocol to detect ACR.[104,105] The goal is to identify and treat episodes of ACR before the onset of allograft dysfunction. Furthermore, since ACR is a widely recognized risk factor for the development of CLAD, it is hoped that early treatment would mitigate this risk. However, this potential benefit has not been examined in the context of a clinical trial. Furthermore, some transplant centers have not adopted a surveillance bronchoscopy protocol, and a number of studies have reported good long-term outcomes without surveillance bronchoscopy.[106,107] Nonetheless, centers that do not perform surveillance bronchoscopy generally have a low threshold to perform a clinically indicated bronchoscopy. Indeed, at one center that stopped performing surveillance bronchoscopy, patients had a similar number of procedures whether they underwent surveillance or clinically indicated bronchoscopy.[108] There is a lack of evidence to guide clinical practice in this area, and transplant centers have developed local protocols for patient follow-up based on experience, expertise, and resources.

Over the past 10 years, there has been a growing interest in the role of humoral immunity in lung transplant rejection. The development of donor-specific antibodies (DSA) to mismatched human leukocyte antigens (HLA) has been increasingly recognized as an important risk factor for the development of CLAD.[109–112] Consequently, some have advocated for screening clinically stable recipients for DSA with the hope that early treatment may improve outcomes.[113–115] Furthermore, screening for DSA identifies patients at increased risk for CLAD who may benefit from closer monitoring and earlier diagnosis. Additionally, maintenance immunosuppression can be optimized in these patients to delay the onset of CLAD. However, although the development of DSA is common early after transplantation,[116] screening and interventions based on the screening results have not been evaluated in a randomized controlled trial, and the benefits of these approaches remain unproven. Recent work in antibody-mediated rejection (AMR) has focused on donor-derived cell-free DNA (ddcfDNA) as a biomarker.[117,118] Allograft injury results in the release of ddcfDNA into the circulation, and this appears to be a sensitive marker for injury especially due to AMR.[118] Elevated levels of ddcfDNA are noted almost 3 months before the onset of clinical AMR, making this in combination with DSA testing potentially very useful tests for clinical monitoring.[118]

IMMUNOSUPPRESSION

Immunosuppression management of the lung transplant recipient immediately following surgery, as well as over the long term, are considered below.

Induction Immunosuppression

Induction immunosuppression is given either during or immediately after transplant surgery depending on the drug. The goal is to prevent early rejection by rapidly suppressing immune responses to the allograft. According to the ISHLT registry report, more than 80% of lung transplant recipients were treated with induction immunosuppression in 2017.[24] This is significantly higher than in 2010 when approximately 50% were treated with induction.[24] The majority of patients are treated with an IL-2 receptor antagonist (e.g., basiliximab), and <10% are treated with polyclonal antithymocyte globulin (ATG) or alemtuzumab.[24] However, benefits of induction immunosuppression, and basiliximab in particular, have not been clearly demonstrated in clinical trials in lung transplantation. In the only multicenter study examining the role of induction immunosuppression after lung transplantation to date, 223 patients at 18 centers were randomized to rabbit ATG or placebo.[119] There was no significant difference in the composite efficacy endpoint of ACR, allograft loss, or death between the 2 groups.[119] There was also no significant difference in the incidence of bacterial, viral, or fungal infections between the 2 groups.[119] In the only other randomized controlled trial comparing rabbit ATG to no induction, the ATG group was significantly less likely to develop mild ACR.[120] However, in a subsequent study of long-term follow-up of the 2 groups, the ATG group only had a lower incidence of ACR in the first 6 months after transplant, but there was no significant difference in the overall incidence of ACR, BOS, or survival between the 2 groups.[121] Another single-center trial randomized patients to muromonab-CD3, equine ATG, or daclizumab (another IL-2 receptor antagonist that is no longer available) and found no significant difference in ACR, BOS, or survival between the 3 groups.[122] A smaller study randomized patients to rabbit ATG or daclizumab and found no significant difference in ACR, BOS, or infections between the 2 groups.[123] More recently, a single-center study demonstrated a significantly lower incidence of ACR with alemtuzumab compared to rabbit ATG.[124] It is noteworthy that although basiliximab is the most commonly used agent for induction after lung transplantation worldwide, there have been no randomized controlled trials to support its use and little evidence to support the use of any induction agent after lung transplantation. An important limitation of clinical trials in lung transplantation is that the sample size is often small, and studies may be underpowered to detect statistically significant differences. Indeed, the largest clinical trial examining the role of induction randomized 223 patients.[119] In an ISHLT registry analysis, which included more than 20,000 patients, induction was associated with a significant survival benefit.[124] However, this finding should be interpreted with caution as confounding variables that may influence survival but are not included in this univariate analysis are not accounted for.

Maintenance Immunosuppression

Maintenance immunosuppression is initiated either immediately before or after the transplant surgery based on institutional protocols and continued lifelong. In general, maintenance immunosuppression is most intensive in the first 6 to 12 months after transplantation and is subsequently tapered to minimize toxicity unless the patient develops late ACR or CLAD. Patients are treated with three classes of drugs: a calcineurin inhibitor (e.g., tacrolimus, cyclosporin A), a cell-cycle inhibitor (e.g., azathioprine, mycophenolate mofetil), and a steroid (e.g., prednisone). Tacrolimus and cyclosporin A inhibit T-cell proliferation by inhibiting calcineurin and decreasing transcriptional activation of proinflammatory cytokine genes, including IL-2, tumor necrosis factor α, and interferon γ. Azathioprine and mycophenolate mofetil block T- and B-cell proliferation by inhibiting purine metabolism. The most common combination reported to the ISHLT registry is tacrolimus, mycophenolate mofetil, and prednisone.[24] Indeed, more than 80% of patients are on tacrolimus and mycophenolate mofetil at the end of the first year after transplantation.[124]

Several randomized controlled trials comparing the efficacy of tacrolimus and cyclosporin A have been conducted over the past 25 years.[125–130] Different induction agents or no induction and different cell-cycle inhibitors have been used in these trials. Additionally, different recipient and donor selection criteria as well as different medical management practices have been used in these trials. Not surprisingly, the results have been somewhat inconsistent. Three trials demonstrated a statistically significant reduction in ACR with tacrolimus,[125,127,129] and 3 demonstrated no significant difference in ACR between the 2 drugs.[126,128,130] Two trials demonstrated a significantly lower incidence of BOS with tacrolimus,[126,130] 1 demonstrated a trend toward a lower incidence of BOS that was not statistically significant with tacrolimus,[129] and 1 demonstrated no significant difference in the incidence of BOS between the 2 drugs.[128] Notably, no significant difference in the incidence of infection has been identified between the 2 drugs in any of the trials, and most importantly, no significant difference in survival has been identified between the 2 drugs in any of the trials.[125–130] However, it should be noted that none of the trials was adequately powered to detect a survival difference, and survival was not the primary endpoint in any of these trials. Three clinical trials comparing the efficacy and safety of azathioprine to mycophenolate mofetil have been conducted in lung transplantation.[131–133] The earliest trial randomized 22 patients to mycophenolate mofetil or azathioprine in combination with cyclosporine A and ATG induction and showed a lower incidence of ACR in the mycophenolate mofetil group, but there was no difference in the incidence of BOS or survival between the 2 groups.[131] Two subsequent, larger studies showed no significant difference in ACR, BOS, or survival between azathioprine and mycophenolate mofetil.[132,133]

Mammalian target of rapamycin (mTOR) inhibitors, including sirolimus and everolimus, have antiproliferative effects beyond their immunosuppressive properties, and this makes them appealing for the prevention of CLAD.[134] Initial experience with sirolimus initiated early after lung transplantation was notable for wound and airway anastomotic dehiscence.[135,136] Since then, a number of clinical trials have examined the role of delayed initiation of mTOR inhibitors in combination with either cyclosporine A or tacrolimus compared to either azathioprine or mycophenolate mofetil.[11,137–139] Two studies demonstrated a lower incidence of ACR with everolimus compared to mycophenolate mofetil,[11,140] but none of the studies showed a lower incidence of BOS or better survival associated with either mTOR inhibitor.[11,137–139] Importantly, there was a high incidence of toxicity including kidney injury, hyperlipidemia, edema, and infections associated with mTOR inhibitors, and drug discontinuation was frequent.

Ideally, clinical practice would be guided by high-quality evidence and carefully designed randomized controlled trials. However, this has been challenging in lung transplantation in spite of many advances in immunosuppression. Clinical trials have been limited by small sample sizes, short duration of follow-up, frequent crossover, and drug discontinuation. Thus, clinical practice has largely been guided by experience and institutional protocols.

PRIMARY GRAFT DYSFUNCTION

PGD is a common early complication after lung transplantation that represents an acute lung injury with clinical, radiographic, and histologic features similar to ARDS.[140,141] The pathogenesis is complex, but ischemia after retrieval from the donor followed by reperfusion at the time of transplantation is the primary cause.[142] Other factors that promote this injury include noncardiogenic pulmonary edema due to donor brain death, aspiration, and ventilator-induced lung injury. In 2005, the ISHLT developed a definition for PGD to standardize the nomenclature and facilitate research at different centers.[143] The definition was subsequently refined in 2016.[140] The definition is based on the presence of radiographic evidence of pulmonary edema and impairment in gas exchange assessed by the Pa_{O_2}:Fi_{O_2} ratio.[140,143] For example, a patient with pulmonary edema on chest x-ray and a Pa_{O_2}:Fi_{O_2} ratio of 180 would have PGD grade 3. In contrast, a patient without pulmonary edema on chest x-ray would have PGD grade 0 regardless of the Pa_{O_2}:Fi_{O_2} ratio.[140,143] PGD is graded at four timepoints over the first 72 h after transplantation (time 0, time 24 h, time 48 h, and time 72 h). Inherent to this definition is the exclusion of other confounding complications that might cause allograft dysfunction including hyperacute rejection, venous anastomotic complications, cardiogenic pulmonary edema, and pneumonia. The definition has been validated in multiple studies.[144,145] The incidence of PGD grade 3 at any timepoint in the first 72 h is approximately 30%.[141] In general, PGD grades are highest immediately after transplantation and improve over the next 72 h.[146]

Treatment for PGD is largely supportive with no specific intervention to ameliorate the lung injury. Not surprisingly, PGD has a significant impact on early morbidity after transplantation. Patients with PGD have a longer duration of mechanical ventilation, a longer duration of ICU and hospital stay, and increased costs.[147] Moreover, patients with PGD grade 3 at 48 or 72 h have a significantly higher risk of death in the first 90 days and 1 year after transplantation.[141] Furthermore, even among those who survive to 1 year after transplantation, PGD grade 3 is associated with an increased risk of death in the long term.[148] Long-term survivors of PGD grade 3 have lower peak lung function and shorter 6-min walk distances after transplantation,[149,150] and this provides them limited functional reserves for later complications. Indeed, all grades of PGD have been associated with an increased risk of BOS, and the risk is highest for those with PGD grade 3.[146,149,151] Limited peak lung function and improvement in functional status, as well as the increased risk of BOS, all contribute to the increased late mortality associated with PGD.

Studies have identified risk factors for the development of PGD grade 3.[141] These include donor smoking history, use of cardiopulmonary bypass during surgery, recipient obesity, pulmonary hypertension, and an underlying diagnosis of sarcoidosis.[141] Some of these factors are potentially modifiable to reduce the risk, whereas others are inherent to the recipient's disease severity. For example, weight loss before listing or transplantation seems feasible if time allows, but secondary pulmonary hypertension reflects the severity of the recipient's disease. More importantly, the interactions between recipient and donor risk factors are complex, and how these should factor into donor selection for a given patient is the focus of ongoing research.

REJECTION

Acute forms of allograft rejection are considered below.

Hyperacute Rejection

Hyperacute rejection, due to preformed DSA to mismatched HLA between the donor and the recipient, is a fulminant form of rejection occurring within the first few hours of transplantation.[152–155] This has become a rare form of rejection in the modern era of lung transplantation, as advances in HLA antibody detection and determination of antibody specificity permits avoiding donors with the reactive HLA.[156] Nevertheless, hyperacute rejection demonstrates that antibodies can cause rejection and fulminant allograft failure. Furthermore, hyperacute rejection illustrates that the vascular endothelium is the focal point of injury and neutrophilic capillaritis is the histologic hallmark.[157] The paradigm for this form of rejection is that DSA bind to HLA on endothelial cells and activate the complement cascade, resulting in endothelial cell necrosis and recruitment of neutrophils to the capillaries with resultant diffuse alveolar damage (DAD).[157] Without aggressive treatment, hyperacute rejection results in allograft failure and death,[158,159] but a number of reports have highlighted recovery with various immunosuppressive treatments.[153,155] Identifying allosensitized patients before transplantation has decreased the incidence of hyperacute rejection. However, this approach narrows the donor pool and prolongs the waiting time for transplantation exposing patients to an increased risk of death.[160] Consequently, programs have attempted desensitization regimens to deplete HLA antibodies before transplantation or intraoperatively with varying success.[161,162]

Acute Cellular Rejection

The incidence of ACR after lung transplantation has been variable in different reports. This is not surprising considering differences in immunosuppressive regimens, patient populations, and variability in interpreting biopsy findings. In the ISHLT registry report, approximately 30% of lung transplant recipients developed an episode of ACR within the first year after transplantation.[24] In a randomized controlled trial comparing mycophenolate to everolimus, the incidence of ACR was 46% in the mycophenolate group and 38% in the everolimus group during the first year after transplantation, but the incidence increased to 54% in the mycophenolate group and 41% in the everolimus group at the end of 3 years.[11] Episodes of ACR, especially milder cases, are often clinically silent, and even if symptoms or clinical signs are present, these are typically nonspecific (e.g., dyspnea, cough, hypoxemia, radiographic infiltrates). Thus, the gold standard for the diagnosis of ACR is transbronchial lung biopsy although the procedure is invasive, and there is significant interreader variability in grading.[163] The histologic criteria for the diagnosis of ACR were originally developed in 1990 by the ISHLT and were revised in 1996 and again in 2007.[164–166] ACR manifests as circumferential perivascular mononuclear cell infiltrates, and the severity is graded based on the intensity of cellular infiltrates around small vessels and extension into the adjacent interstitium.[166] Minimal ACR (grade A1) is

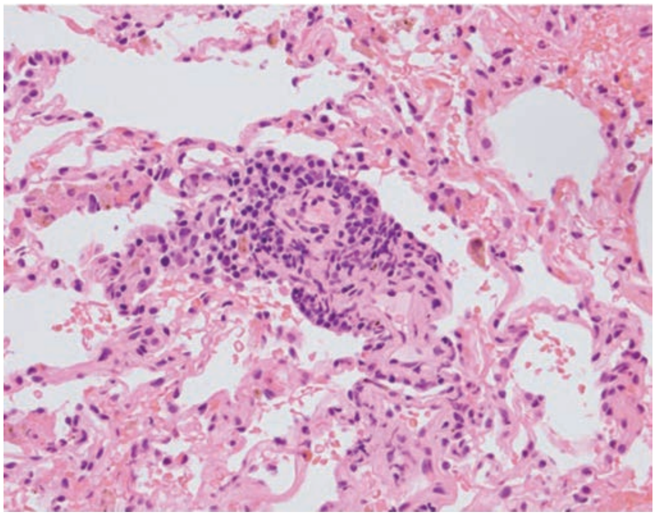

Figure 106-1 Transbronchial lung biopsy demonstrating mild acute cellular rejection (grade A2) (400×). A cuff of mononuclear cells circumferentially surrounds small vessels and expands the vascular adventitia.

characterized by scattered perivascular mononuclear cell infiltrates that are 2 to 3 cells thick and not readily visible on scanning magnification.[166] Mild ACR (grade A2) is more obvious on low power and is characterized by more frequent perivascular infiltrates expanding the vascular adventitia.[166] Figure 106-1 illustrates an example of ACR grade A2. Eosinophils and endothelialitis also may be seen. Moderate ACR (grade A3) is clearly visible at scanning magnification, and the infiltrates extend into the adjacent interstitium.[166] The infiltrating cells often include eosinophils and neutrophils in ACR grade A3. Lastly, severe ACR (grade A4) is characterized by diffuse infiltrates, necrotizing vasculitis, and DAD.[166]

ACR is most commonly seen in the first 3 to 6 months after transplantation, but late episodes beyond the first year also may occur.[167] The mainstay of treatment is bolus methylprednisolone (10–15 mg/kg daily for 3 days) and optimization of the maintenance immunosuppressive regimen because ACR is an indication of active alloimmune responses and a possible portent of poor long-term outcomes. Indeed, ACR has consistently been identified as an important risk factor for CLAD.[167–170] However, no study has demonstrated that treatment for ACR mitigates the risk of CLAD. In general, a follow-up bronchoscopy with transbronchial lung biopsies is indicated 3 to 6 weeks after an episode of ACR to exclude persistent ACR or progression to higher grade ACR. Approximately 25% of patients have persistent ACR at follow-up.[171] Treatment for persistent ACR is variable across centers, and this is often individualized based on the patient's clinical history and risk profile.

■ Lymphocytic Bronchiolitis

Airway inflammation often accompanies higher grades of ACR. Lymphocytic bronchiolitis represents an airway-focused acute rejection pathology that is associated with a high risk of subsequent BOS.[172] However, exclusion of infection as the cause of airway inflammation is necessary to consider lymphocytic bronchiolitis a form of rejection. Two grades of lymphocytic bronchiolitis are defined in the latest ISHLT criteria.[166] Grade B1R is defined as submucosal peribronchiolar mononuclear cell infiltrates without epithelial cell damage or intraepithelial lymphocytic infiltration. Grade B2R is defined as intense inflammation with activated mononuclear cells and eosinophils with epithelial cell ulceration and intraepithelial lymphocytic infiltration. There is little consensus on the optimal management of isolated lymphocytic bronchiolitis without ACR, and cases refractory to high-dose methylprednisolone have been reported to progress rapidly to BOS.[173] Progression of respiratory bronchiolar epithelial ulceration and necrosis to fibrosis and luminal obliteration, characteristic of OB, is readily understandable.

■ Antibody-mediated Rejection

Over the past 10 years, AMR has been increasingly recognized as a form of lung rejection. Although hyperacute rejection was widely accepted as a form of lung rejection more than 25 years ago, cases of AMR occurring beyond the immediate posttransplant period were not readily recognized. The diagnosis of AMR is difficult and requires a multidisciplinary approach and a high index of suspicion. While the diagnosis of ACR is based solely on pathology, the histologic features of AMR are nonspecific patterns of lung injury.[174] Although neutrophilic capillaritis raises suspicion for AMR, this is not a sensitive or consistent finding.[157] The ISHLT definition for AMR is based on experience in kidney transplantation. Definite AMR is defined as clinical allograft dysfunction, circulating DSA, pathology of acute lung injury, capillary C4d deposition, and the exclusion of other possible causes of allograft dysfunction.[174] C4d deposition indicates activation of the complement cascade, but this has been an inconsistent and nonspecific finding in pulmonary AMR.[175–177] The ISHLT definition allows that AMR may be diagnosed confidently in the absence of C4d deposition, although this is still considered probable AMR.[174] Commonly seen histologic abnormalities include DAD, acute pneumonitis, neutrophilic capillaritis, and organizing pneumonitis.[178,179] Figure 106-2 illustrates acute pneumonitis and neutrophilic capillaritis.

The management of AMR is based on experience in kidney transplantation. There is no consensus on the optimal regimen, and different centers use different protocols. In general, treatment is focused on antibody depletion and blocking the effect of antibodies on the allograft. Typically, regimens consist of multiple concomitant treatments including various combinations of plasma exchange, intravenous immune globulin, rituximab, bortezomib, carfilzomib, and eculizumab.[175,176,178–180] Studies illustrate that the acute episode of allograft dysfunction may be reversible in some cases, but there is a high incidence of CLAD and long-term survival after AMR is limited.[175,176,178–180] Additional studies are necessary to improve the management of AMR, and ideally, these would compare various treatment regimens head-to-head to better inform clinical practice.

CHRONIC LUNG ALLOGRAFT DYSFUNCTION

CLAD is the leading cause of death beyond the first year after lung transplantation.[24] Chronic and progressive lung allograft dysfunction leading to respiratory failure was recognized as a serious barrier to long-term survival after combined heart–lung transplantation in the early 1980s.[181] Although histologic findings of OB and an obstructive ventilatory defect were prominent features, a concomitant restrictive ventilatory defect and diffuse interstitial and pleural fibrosis also were recognized.[181,182] These early findings from 35 years ago presage our current paradigm of CLAD after lung transplantation. Today, we recognize CLAD as chronic rejection after lung transplantation with two phenotypes: bronchiolitis obliterans syndrome (BOS) and restrictive allograft syndrome (RAS).[112,13]

■ Bronchiolitis Obliterans Syndrome

Following the recognition of CLAD after combined heart–lung transplantation, BOS received most of the attention of clinicians and researchers in lung transplantation since it was the most common and predominant form of CLAD. OB is the histologic hallmark of BOS and is characterized by fibroproliferative scarring of membranous and respiratory bronchioles. Figure 106-3 illustrates an example of OB after lung transplantation. However, histologic confirmation of OB is difficult with transbronchial lung biopsies because of the patchy nature of the lesion and the small size of biopsies. Consequently, BOS, diagnosed and staged according to decrements in spirometry, is the clinical surrogate for OB.[12,183] Baseline lung function is defined as the average of the two highest FEV_1 measurements after transplantation, and BOS is defined as a persistent ≥20% decline in FEV_1.[12,183] Progressive stages of BOS are defined according to the magnitude of decline in FEV_1 from baseline. Clinically, BOS presents with deteriorating allograft function. Symptoms may be absent during the early stages. Therefore, frequent pulmonary function testing is recommended as part of long-term monitoring of patients. When symptoms are present, they typically include dyspnea with exertion or cough. Imaging studies are usually unrevealing in the early stages, but computed tomography may demonstrate signs of air trapping or ground glass opacities. Imaging later stages of BOS may reveal bronchial wall thickening and bronchiectasis. However, standard computed tomography is an insensitive tool to diagnose or stage BOS.[184]

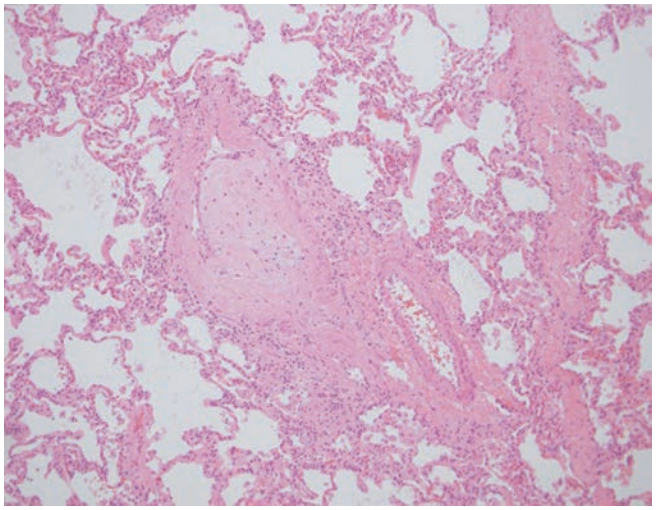

Figure 106-3 Explanted lung pathology illustrating obliterative bronchiolitis after lung transplantation (100×). The lumens of respiratory and membranous bronchioles are obliterated with fibrous connective tissue.

BOS is common, and its incidence increases over time after transplantation. In the ISHLT registry, approximately 20% developed BOS within 2 years, 30% developed BOS within 3 years, and 50% developed BOS within 5 years of transplantation.[24] Likewise, in an international multicenter randomized controlled trial comparing everolimus to mycophenolate, the incidence of BOS at 3 years was 30%.[11] Unfortunately, BOS typically follows a progressive clinical course with ongoing decline in lung function. In a recent study, the largest decline in lung function was seen in the first 6 months after diagnosis, and a ≥10% decline was associated with significantly higher risk of allograft loss.[185] Not surprisingly, BOS is associated with symptoms of anxiety and depression and decreased health-related quality of life.[186,187]

The efficacy of treatment for BOS has been largely disappointing. Long-term treatment with azithromycin has been effective in some patients. In the earliest report, 5 of 6 patients had a significant improvement in lung function after initiating azithromycin.[188] In a randomized controlled trial, 9 of 23 patients in the azithromycin group had a ≥10% increase in FEV_1 compared to none of the patients in the placebo group, although there was no significant difference in FEV_1 between the 2 groups in the intention-to-treat analysis at the end of the study.[189] Azithromycin is now widely accepted as the first-line treatment for BOS because of these results and its ease of administration and low side-effect profile. However, most patients have progressive disease. Other treatment options include ATG and extracorporeal photopheresis (ECP). Treatment with ATG for BOS dates back to the 1990s with mixed results. In a recent retrospective study, 43 of 108 patients treated with ATG had an improvement in FEV_1 in the 6 months after treatment, although the improvement was marginal.[190] ECP is an immunomodulatory treatment used for cutaneous T-cell lymphoma, graft-versus-host disease, and rarely for the prevention of cardiac allograft rejection.[191,192] Blood is separated into leukocyte-enriched and leukocyte-depleted components, and the leukocyte-enriched component is irradiated with ultraviolet light ex vivo; this results in decreases in proinflammatory cytokines, increases in anti-inflammatory cytokines, and increases in tolerogenic regulatory T cells.[193] Multiple retrospective studies have shown improvement in the rate of decline in lung function, and 1 study showed that 25% of patients have an improvement in FEV_1 in the 6 months after therapy.[193,194] Other possible interventions include total lymphoid irradiation, montelukast, and, ultimately, retransplantation.[195–199] Only a small minority of patients who have advanced BOS are candidates for retransplantation. In most cases, BOS follows a progressive clinical course ultimately resulting in chronic respiratory failure and death with a median survival of 2.5 years after the diagnosis.[200] Clearly, better treatment options for BOS are necessary to improve clinical outcomes. There are currently multiple ongoing clinical trials investigating novel treatments including aerosolized cyclosporin, nintedanib, pirfenidone, and itacitinib (a Janus-associated kinase 1 inhibitor).

■ Restrictive Allograft Syndrome

Historically, some cases of chronic allograft dysfunction did not fit the strict definition of BOS because of a predominantly restrictive ventilatory defect and fibrotic opacities on imaging studies. In 2005, a two-center study described a small cohort of patients who developed progressive allograft dysfunction characterized by upper lobe fibrosis and restrictive ventilatory abnormalities.[201] The histology was characterized by dense fibrosis with occasional OB and bronchiolitis obliterans organizing pneumonia.[201] In 2011, the Toronto Lung Transplant Program coined the term *restrictive allograft syndrome (RAS)* to characterize this unique phenotype of CLAD.[202] In this cohort, 30% of patients with CLAD had the RAS phenotype, which was characterized by a decline in total lung capacity (TLC), interstitial or ground glass opacities on computed tomography, and a pathology of DAD

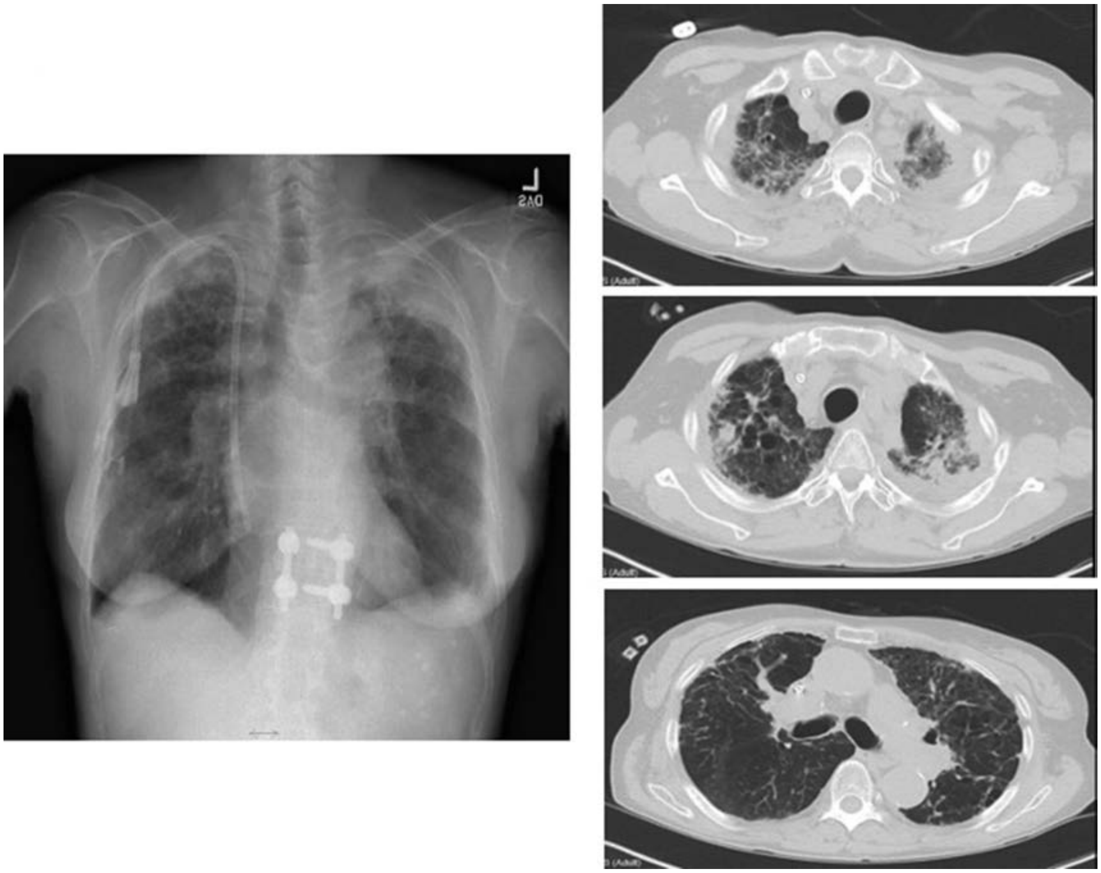

Figure 106-4 Chest radiograph illustrating coarse interstitial and airspace opacities in the upper lobes and pleural thickening in a patient with restrictive allograft syndrome. CT images of the chest show upper lobe architectural distortion, fibrosis, bronchiectasis, and pleural thickening.

and extensive fibrosis.[202] Concomitant OB was noted in some cases. Likewise, in a pathologic study of RAS, pleuroparenchymal fibroelastosis was the predominant feature in 15 of 16 patients, but notably, 14 had concomitant OB.[203] Figure 106-4 demonstrates characteristic imaging findings of RAS including upper lobe fibrosis and pleural thickening. Importantly, patients with RAS have a significantly worse survival after the diagnosis of CLAD than those with BOS; the median survival after the diagnosis of RAS was 541 days compared with 1421 days after the diagnosis of BOS.[202] Based on these findings, the ISHLT reclassified CLAD into the two current phenotypes.[12,13] Furthermore, it is recognized that some patients may have features of both BOS and RAS, and that some patients may have BOS at the onset of CLAD but evolve into a “mixed” phenotype over time as they develop signs of interstitial fibrosis and ventilatory restriction.[202] Therapeutic interventions for RAS have largely been disappointing. Not surprisingly, antifibrotic agents such as pirfenidone and nintedanib have been used with mixed results.[204–207] However, these reports have been limited to isolated cases and small case series where antifibrotics are used as a salvage therapy for refractory RAS. A randomized clinical trial using pirfenidone for RAS is currently recruiting participants. Clearly, better treatment options are necessary to improve clinical outcomes for patients with RAS.

INFECTIONS

Infections are common complications at all timepoints after lung transplantation. In fact, infections are common causes of death at all timepoints after transplantation, accounting for 15% to 30% of deaths according to the ISHLT registry.[24] Impairment in mucociliary clearance and cough, loss of lymphatic drainage, and therapeutic immunosuppression after lung transplantation increase the risk of respiratory infections. In addition, the constant exposure of the lung allograft to the environment further increases the risk of respiratory infections. In the immediate period after transplantation, donor-transmitted, recipient-derived, and nosocomial infections are most common.[208] *Pseudomonas aeruginosa* is a common cause of pneumonia in this early period after transplantation, and early nosocomial infections are associated with an increased risk of mortality.[209,210] Extrapulmonary nosocomial infections include surgical site infections, empyema, and *Clostridium difficile* colitis.[211–213] Surgical site infections are typically due to skin flora (*Staphylococcus* species or *Candida albicans*) and are associated with delayed chest closure.[214]

The risk of opportunistic infections is highest in the first 6 to 12 months after transplantation. The risk of CMV infection depends on the sero-status of the donor and the recipient, with seronegative recipients of lungs from seropositive donors having the highest risk. In general the risk of CMV infection wanes beyond the first year after transplantation, but patients with short telomeres have impaired CMV immunity and remain at increased risk of infection.[215,216] Extended prophylaxis with valganciclovir has become common practice; however, this is complicated by leukopenia in many cases.[101] Patients in certain geographic locations are at risk for endemic fungal infections, such as coccidioidomycosis, histoplasmosis, and blastomycosis. Prophylactic regimens are variable depending on local practices and risks. Invasive mold infections are uncommon but are associated with significant morbidity and mortality.[217] The lungs are the most commonly affected site, and *Aspergillus* is the most commonly isolated mold.[217] There is no consensus on the role of universal antifungal prophylaxis. Some studies suggest that this approach is superior to targeted prophylaxis, but others have not confirmed this benefit.[218,219] Thus, antifungal prophylactic regimens vary across centers. Most patients are treated with antibiotic prophylaxis against *Pneumocystis jiroveci*.

Community-acquired respiratory viral (CARV) infections are common at all timepoints after transplantation.[220] CARV infections cause a spectrum of disease in lung transplant recipients ranging from pharyngitis and rhinitis to bronchiolitis and pneumonia. Both upper and lower respiratory tract infection have been associated with a decline in lung function during the acute phase of infection, and many cases require hospitalization.[221] Beyond the acute phase of CARV infection, patients are at increased risk of acute rejection, infection with *Pseudomonas aeruginosa*, CLAD, and death following acute infection.[220–222] These serious complications indicate progressive respiratory disease following CARV infection, but the mechanism remains poorly understood. COVID-19 causes severe disease in some lung transplant recipients.[223,224] An early case series of 32 patients from New York City reported a 34% mortality during the acute phase of the infection.[224] Long-term consequences of COVID-19 infection on allograft function and survival remain to be seen.

MALIGNANCY

Therapeutic immunosuppression after solid organ transplantation is associated with an increased risk of malignancy.[225] This is especially true for malignancies linked to viral infections such as non-Hodgkin lymphoma and Epstein-Barr virus (EBV). In the ISHLT registry, the incidence of any malignancy is 5% among 1-year survivors; approximately 35% of these are skin cancers and 18% are lymphoma.[24] Among 5-year survivors, the incidence increases to 20%, and more than 70% are skin cancers, 10% are lymphoma, and 27% are other cancers.[24] Among 10-year survivors, the incidence increases to 32%, and the distribution of cancer types is similar to 5-year survivors.[24] Overall, malignancy is the cause of death of approximately 9% of lung transplant recipients who survive between 1 and 3 years, 13% of 3- to 5-year survivors, and 15% of 5-year survivors.[24] Skin cancers are primarily squamous cell carcinoma and basal cell carcinoma, and these are usually managed successfully with resection. However, recurrence or second primaries are common, and risk factors include age, white race, sun exposure, prolonged treatment with voriconazole, and a history of skin cancer before transplantation.[226–228] Some patients have a particularly aggressive clinical course, and in one report, 5% died from skin cancer.[226]

Posttransplant lymphoproliferative disorders (PTLD) are a group of abnormal lymphoid proliferations after transplantation that result from immunosuppression. B-cell proliferation and non-Hodgkin lymphoma are more common, although T-cell PTLD also is recognized. PTLD is often associated with EBV; infected B cells elicit a cytotoxic T-cell response to control the infection. This host response results in the syndrome of infectious mononucleosis. Latently infected B cells that persist may give rise to PTLD when T-cell responses wane under the influence of therapeutic immunosuppression. However, EBV-negative PTLD is increasingly recognized, and the tumor's EBV status does not appear to impact prognosis or treatment response.[229] Nevertheless, recipient EBV status is an important risk factor for developing PTLD, and EBV-seronegative recipients of lungs from seropositive donors are at significantly increased risk.[230,231] The use of induction immunosuppression also is associated with an increased risk of PTLD.[232] Approximately half of the cases of PTLD present in the first year after transplantation, and these are more likely to involve the allograft or mediastinal or hilar lymph nodes.[233,234] In contrast, later cases are more likely to be extrathoracic or disseminated.[233,234] **Figure 106-5** illustrates imaging

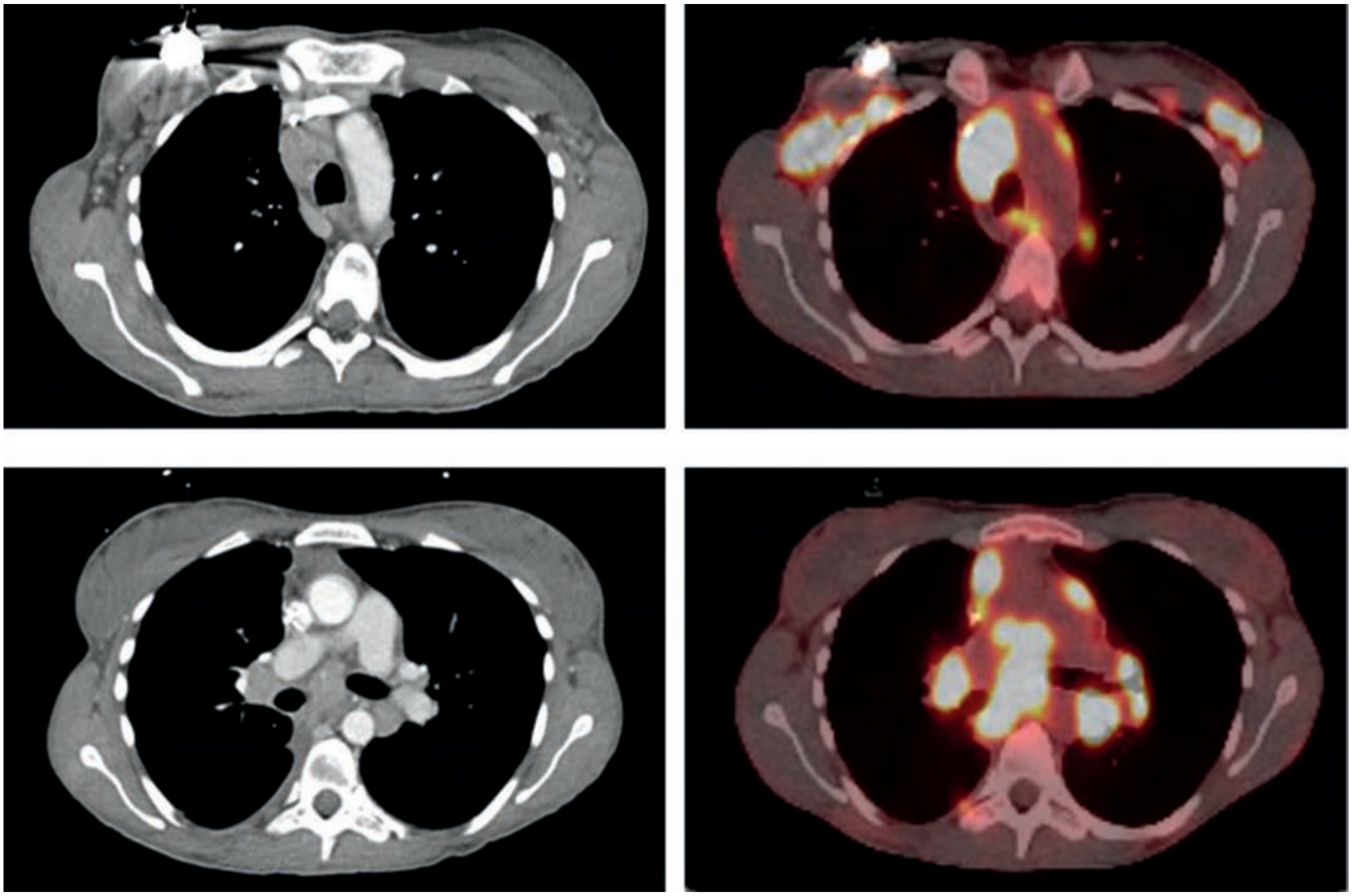

Figure 106-5 Chest CT from a patient with posttransplant lymphoproliferative disorder demonstrating lymphadenopathy in the paratracheal, subcarinal, and right hilar regions. The lymphadenopathy was fluorodeoxyglucose (FDG)-avid on positron emission tomography.

studies from a lung transplant recipient who presented with fever and malaise for several weeks; diffuse fluorodeoxyglucose (FDG)-avid lymphadenopathy was noted. Liver biopsy confirmed diffuse large B-cell lymphoma (Fig. 106-6).

Lung transplant recipients are at increased risk for lung cancer. This is especially true for single lung recipients who were former smokers.[235,236] Underlying diagnoses of pulmonary fibrosis and COPD are risk factors among single lung recipients, and the cancers typically develop in the native lung. Although lung cancer after lung transplantation presents at the localized stage more frequently than in the general population, the prognosis is poor.[235,237] Lung cancer in the allograft is uncommon because of stringent donor selection criteria.

SURVIVAL

Survival after lung transplantation remains disappointing. According to the ISHLT registry, which includes more than 50,000 patients worldwide, there has been steady improvement in survival over time.[24] In the most recent era between 2010 and 2017 the median survival was 6.7 years, which is significantly better than the median survival between 2002 and 2009 (6.5 years) and 1992 and 2001 (4.7 years).[24] This improvement is seen primarily in the first year after transplantation, as survival curves for each era diverge very early after transplantation but then become nearly parallel. These findings are attributed to improvements in donor and recipient selection and management, refinements in surgical techniques, and advances in intraoperative and early postoperative care. In contrast, survival beyond the first year after transplantation has been limited by persistently high incidences of CLAD and infection, which remain leading causes of death. It is noteworthy that survival in the most recent era is better than previous eras in spite of generally transplanting older and sicker patients and using more donors who were previously considered marginal. This underscores the impact of the advancements in clinical practice over the past 20 years.

The ISHLT registry analyzes predictors of survival using univariate and multivariate models.[24] However, even multivariate models only identify statistical associations, and these do not imply causation. Nonetheless, these identify clinically relevant factors that are associated with survival. Factors associated with better survival include the most recent era of transplantation, bilateral lung transplantation, and an underlying diagnosis of CF or lymphangioleiomyomatosis.[24] In contrast, CMV-seronegative recipients from seropositive donors, donor history of hypertension or diabetes, retransplantation, and poor recipient functional status before transplantation are associated with worse survival.[24] Likewise, increasing recipient age is associated with worse survival although the relationship is not linear, and the risk begins to increase beyond the age of 55 years.[24]

CONCLUSIONS

Lung transplantation evolved from an experimental surgery to the mainstay treatment for patients with advanced lung disease. Long-term outcomes remain disappointing, and patient survival is significantly lower than that of other solid organ transplant recipients. CLAD and infections are the leading causes of death beyond the first year after transplantation. A role for humoral immune responses in the development of CLAD is increasingly recognized. Clearly, better treatments are necessary to prevent and delay the development and progression of CLAD without increasing the risk of infections and other toxicities. Likewise, studies to develop a better understanding of lung rejection and CLAD are needed to improve clinical practice.

CHAPTER 107

Genetic and Molecular Changes in Lung Cancer: Prospects for a Personalized Pharmacologic Approach to Treatment

Howard Y. Li
Jeffrey A. Kern

INTRODUCTION

The discovery that some lung cancers harbor specific somatic mutations that are essential for malignant growth (i.e., “driver mutations”), which lead to gain of function of oncogenes or loss of function of tumor suppressor genes, and the discovery that antitumor T cell responses are regulated by immune checkpoints, have paved the way for molecularly targeted, personalized lung cancer therapy. Lung cancer is classified based on histologic features as either non–small-cell lung cancer (NSCLC; approximately 85% of all lung cancers) or small-cell lung cancer (SCLC; approximately 15%).[1] NSCLCs are further divided histologically as adenocarcinoma, squamous cell carcinoma, and large cell carcinoma. Various chemotherapeutic regimens have been used to treat different NSCLC histologic subtypes. But with the realization that NSCLC is a collection of diseases that are identifiable by specific molecular abnormalities, personalized therapy is achievable for a subset of patients with NSCLC (Fig. 107-1).

While clearly promoting the oncogenic state, driver mutations are also commonly associated with “oncogene addiction,” or dependency of some cancers on one gene for the maintenance of the malignant phenotype. These dependencies, which are specific to an individual’s cancer, are absent in normal cells. Inhibition of “druggable” proteins coded for by driver mutations, such as the BCR-ABL fusion protein with imatinib in chronic myelogenous leukemia or human epidermal growth factor receptor 2 (HER2) with trastuzumab in breast cancer, are prime examples of successful therapeutic targeting of critical signaling nodes in cancer.

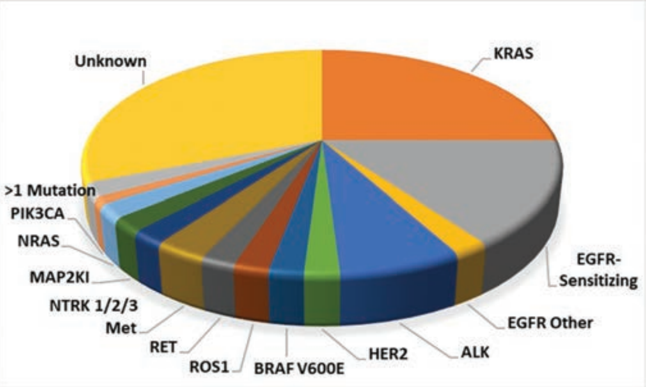

Figure 107-1 Driver mutations in lung adenocarcinoma.

Between 1980 and 2000, NSCLC oncogenic drivers that were investigated included mutations in the Kirsten rat sarcoma viral oncogene homolog (*KRAS*) and protein 53 (*p53*) genes, loss of specific chromosomal loci, loss of heterozygosity, and DNA methylation of tumor suppressor genes. In 2004, driver mutations in the epidermal growth factor receptor (*EGFR*) gene, a membrane-bound receptor tyrosine kinase (RTK) that regulates cell growth, were discovered in NSCLC, especially in adenocarcinomas.[2–4] These *EGFR* driver mutations resulted in a receptor with dysregulated signaling driving cell growth and the oncogenic phenotype, but also led to a cellular dependence on EGFR RTK signaling. Thus, these mutations were strongly associated with therapeutic sensitivity to tyrosine kinase inhibitor (TKI) drugs that inhibited EGFR’s tyrosine kinase (TK) function. In 2007, translocation of the echinoderm microtubule-associated protein-like 4 (*EML4*) translocation to the anaplastic lymphoma kinase (*ALK*) gene resulting in an *EML4-ALK* fusion gene[5] and chromosomal rearrangements of the gene encoding ROS1 proto-oncogene receptor tyrosine kinase (*ROS1*)[6] were identified in NSCLC. As with EGFR, the *EML4-ALK* translocation and *ROS1* oncogenic fusion resulted in dysregulated TK signaling, again driving cell growth and the oncogenic phenotype, as well as cellular dependencies on EML4-ALK and ROS1 signaling, respectively. Targeting ALK and ROS1 with TKIs has been shown to be highly effective in NSCLCs that express these driver mutations. BRAF^{V600E} substitution was identified in melanomas and nonsquamous NSCLC,[7] and this discovery led to the development of BRAF-targeted drugs. MET exon 14 skipping mutations and RET translocations occur in approximately 3% and 2% of nonsquamous NSCLCs, respectively. Similar to other RTK driver mutations, NSCLCs with MET exon 14 skipping mutations and RET translocations demonstrate sensitivity to TKIs. In contrast with other lung cancer patients, who tend to be older with extensive smoking history, RTK mutations are more commonly found in female never-smokers of East Asian origin with adenocarcinoma histology.

Recent advances in the understanding of T lymphocyte immunobiology have been instrumental in advancing therapeutic strategies to overcome tumor immune escape and represent a fundamental change in cancer therapy. Instead of targeting a patient’s cancer, as current chemotherapy does, immunotherapy targets the host immune cells and removes inhibitory pathways that block effective antitumor T-cell responses. A breakthrough in cancer therapy was the development of pharmacologic immune checkpoint inhibitors. Designed to interfere with naturally occurring T lymphocyte inhibitory pathways that constrain reactivity, immune checkpoint blockade releases limits on the activation and maintenance of effector T lymphocyte function. Evidence that these inhibitory T lymphocyte pathways are overactive in NSCLC led to the realization that NSCLC is an exciting target of immune-based therapies. Checkpoint inhibitors targeting programmed cell death 1 (PD-1) and programmed cell death ligand 1 (PD-L1) yielded unprecedented and durable, long-lasting responses in a significant subset of cancer patients, leading to U.S. Food and Drug Administration (FDA) approval of these checkpoint inhibitors for multiple cancer types, including NSCLC.

These discoveries illustrate that molecular biologic findings in NSCLC and the host can be directly linked to the development of novel therapies and thereby improve the survival rates of lung cancer patients. Although 5-year survival rates for lung cancer remain low (25% for NSCLC, 7% for SCLC), overall mortality from lung cancer declined from 2013 to 2016.[8] Whereas mortality from SCLC declined almost entirely as a result of declining incidence, which has been attributed to reduced cigarette smoking rates, mortality from NSCLC decreased faster than the incidence of NSCLC.[9] The reduction in mortality from NSCLC is likely due to both reductions in incidence along with treatment advances, specifically the development and use of targeted therapies for oncogene-driven lung adenocarcinoma. Unfortunately, molecularly targeted drugs for SCLC have not been identified. Although some SCLC patients respond to PD-L1 immune checkpoint blockade, only a small subset derives prolonged benefit. Thus, a better understanding of SCLC is needed to identify therapeutic vulnerabilities that may lead to the development of rationally targeted approaches for SCLC.

As new pathways and mechanisms that drive lung cancer are identified, existing agents that have not been previously considered for lung cancer can now be tested, or new drugs targeting the affected pathways can be developed. These discoveries allow a patient's therapy to be individualized to the molecular elements that drive their disease and treatment with agents that best target the characteristics of their cancer, offering higher response rates and improvements in survival. However, hundreds of mutations occur in a cancer cell and not all of them are functionally important or suitable targets for personalized therapy. To improve the chances of success in the development of personalized medicine for lung cancer, we need to identify a functionally important target or pathway, a biomarker to identify and follow therapeutic response, the appropriate therapeutic endpoint, and the mechanisms of resistance to personalized therapy, both primary and acquired.

TUMOR MOLECULAR BIOLOGY LEADING TO TARGETED THERAPY

Lung cancer results from the dysregulation of cellular processes that control cell cycling and death, allowing unrestricted cell growth (Fig. 107-2A). Growth-promoting pathways that promote NSCLC include activating mutations in tyrosine kinases such as EGFR, ALK, ROS1, BRAF, MET, and RET; and activating mutations in intracellular guanosine triphosphatases (GTPases) such as KRAS. Although oncogenic driver mutations are critical for lung carcinogenesis, they also lead to tumor cell vulnerabilities that have paved the way for the development of targeted therapeutics.

■ Receptor Tyrosine Kinases

Membrane-bound RTKs share a common general structure composed of an extracellular region that contains a ligand-binding domain, an extracellular juxtamembrane region, a hydrophobic transmembrane domain, a cytoplasmic TK domain, and a cytoplasmic tail with tyrosine residues that serve as sites for receptor phosphorylation. Ligand binding results in receptor dimerization and activation of the receptor's TK domain, leading to phosphorylation of the receptor's tyrosine residues. This, in turn, results in recruitment of signaling molecules to the phosphorylated tyrosine residues and coupling to downstream effectors, eventually leading to biologic responses. RTK activity in nonmalignant cells is normally under tight temporal and spatial regulation by the receptor and its ligand, which safeguards against unwanted activation. Driver mutations in the membrane-bound RTKs result in dysregulated signaling or in a receptor that cannot be shut off. RTK activation in cancer may occur via overexpression of wild-type receptor due to gene amplification (resulting in excess signaling), excess ligand production with receptor overstimulation, activating mutations, translocations resulting in activated fusion proteins, or reduced receptor downregulation.

The prototypical RTKs involved in lung cancer are members of the ERBB family. The ERBB family of RTKs includes ERBB1 (EGFR; HER1), ERBB2 (HER2), ERBB3 (HER3), and ERBB4 (HER4). In the lung, these RTKs are expressed by the pulmonary

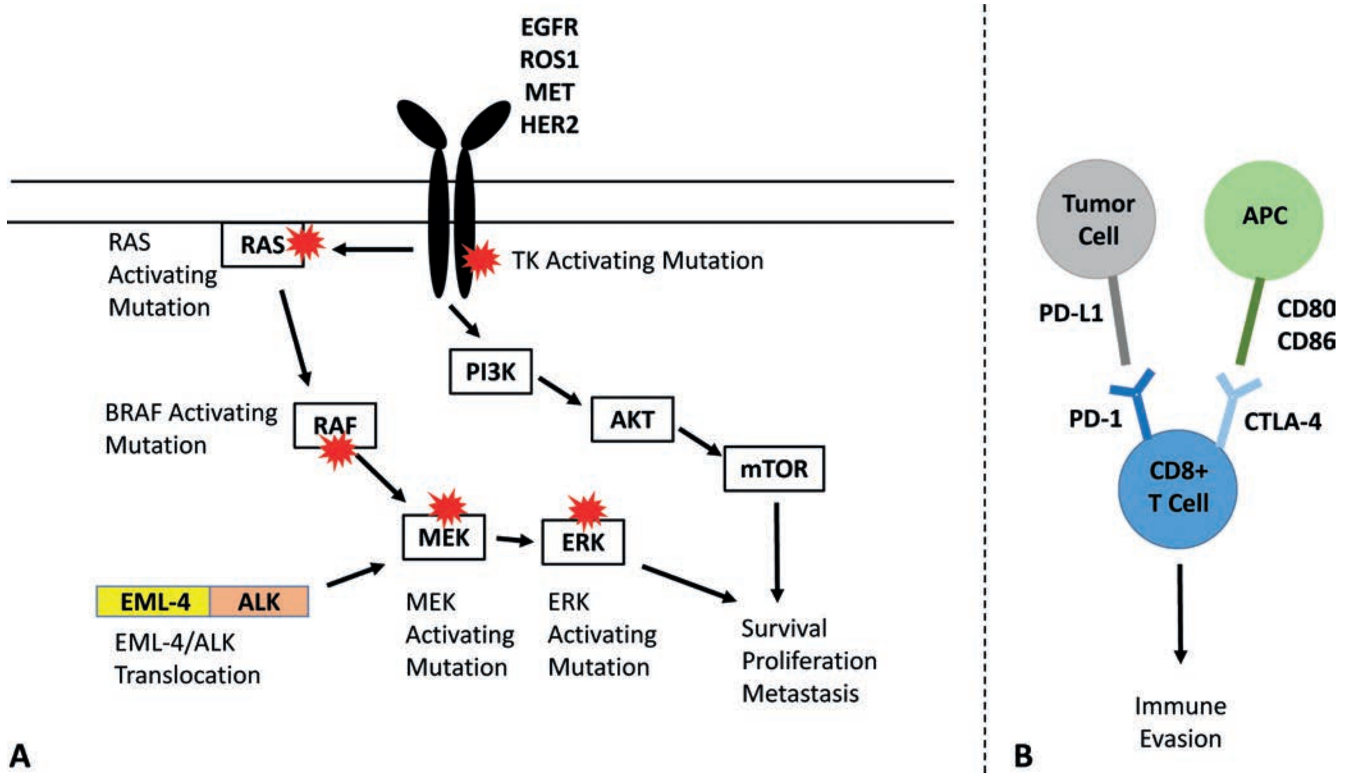

Figure 107-2 Overview of targetable pathways in lung cancer. **A.** Oncogenic driver mutations lead to ligand-independent activation of downstream signaling pathways, leading to cellular survival, proliferation, and metastasis. **B.** PD-1 and CTLA-4 are immune checkpoint receptors expressed by CD8+ T cells that are exploited by lung cancer as an immune evasion mechanism.

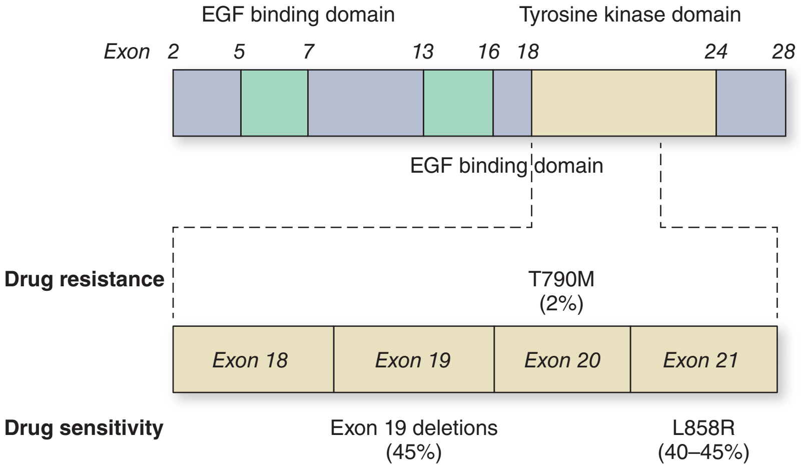

Figure 107-3 Epidermal growth factor receptor (EGFR) mutations in NSCLC. This representation of EGFR shows the distribution of exons in the epidermal growth factor ligand-binding domains and tyrosine kinase domain (TK). Exons 18–21 in the TK region where the relevant mutations are located are expanded and the most common mutations associated with EGFR TK inhibitor sensitivity and resistance are shown.

epithelium (e.g., alveolar type II cells and bronchial cells) and fibroblasts. Members of the epidermal growth factor family of peptide hormones serve as ligands for ERBB RTKs, and include epidermal growth factor (EGF), transforming growth factor α, betacellulin, and epiregulin for ERBB1; and the neuregulins for ERBB3 and ERBB4. Ligand binding activates the receptor and multiple intracellular signaling pathways that govern fundamental cellular processes including proliferation, cell migration, metabolism, and survival. For example, phosphorylation of ERBB RTKs results in activation of growth factor receptor–bound protein 2 (Grb2) and Son of Sevenless (SOS), which ultimately leads to phosphorylation and activation of RAS. Activation of the RAS/RAF/MEK/extracellular signal–regulated kinase (ERK) pathway leads to cell proliferation. In contrast, activation of the phosphoinositide 3 kinase (PI3K)/AKT pathway by ERBB RTK signaling results in prolonged cell survival via the expression of mitochondrial antiapoptotic proteins. Thus, dysregulation in an RTK pathway can give a selective growth and survival advantage to a cell, resulting in clonal expansion and tumorigenesis. Sequencing a patient's lung cancer for *EGFR* or *HER2* gene mutations can identify specific alterations in this pathway, allowing the use of targeted chemotherapy agents.

Epidermal Growth Factor Receptor

Small molecule agents have been developed to inhibit EGFR kinase signaling by blocking the intracellular TK domain. The first of these EGFR TKIs, gefitinib and erlotinib, began testing in clinical trials in the early 2000s. Both gefitinib and erlotinib are orally administered agents that bind noncovalently at the ATP-binding pocket of EGFR, competing with ATP binding, thereby suppressing EGFR phosphorylation and downstream signaling. Initial randomized studies in NSCLC with EGFR TKIs in combination with standard first-line platinum-based chemotherapy were negative. However, in the TRIBUTE trial of carboplatin and paclitaxel with erlotinib or placebo, 116 patients who reported that they had never smoked had a prolongation in survival with erlotinib treatment (22.5 months) compared to placebo treatment (10.1 months; $p = 0.01$), suggesting that treatment with erlotinib improved survival in never smokers.[10]

In 2004, as a result of basic research to understand this dramatically different response rate to EGFR TKI therapy, several groups reported the discovery of a collection of activating mutations in the TK domain of EGFR that correlated with a high likelihood of response to EGFR TKIs.[2–4] Approximately 90% of observed *EGFR* gene mutations are either small in-frame deletions in exon 19 clustered around the catalytic site of the receptor, or an amino acid substitution from a leucine to an arginine at position 858 in EGFR (L858R), which lies within the TK activation loop in exon 21 (Fig. 107-3). In cells harboring *EGFR* gene mutations, the mutated receptor leads to enhanced AKT signaling and downstream activation of antiapoptotic and prosurvival signals. The location of *EGFR* gene mutations within critical residues of the tyrosine kinase domain leads to an altered physical structure, enhanced drug binding, and sensitivity to EGFR TKIs. Virtually all EGFR inhibitors, including first-generation (gefitinib and erlotinib), second-generation (afatinib), and third-generation (osimertinib) TKIs demonstrate better responses in EGFR-mutant NSCLCs carrying exon 19 deletions compared with L858R mutations.[11,12] Other types of *EGFR* TK domain mutations have been reported. In contrast to the more common exon 19 deletions and L858R mutation, some of these minor mutations are associated with resistance to EGFR TKIs.[13]

Many of the patients harboring these mutations demonstrated rapid, nearly complete reduction of their cancers that persisted for up to several years. *EGFR* gene mutations were much more commonly found in female never-smokers of East Asian origin with adenocarcinoma histology. Whereas the incidence of *EGFR* mutations in lung adenocarcinomas among Asians is 47%, the incidence in North American and Western European patients is approximately 18%.[14] Although the strongest predictors of *EGFR* mutation status are female sex and absent or low smoking history, a large number of EGFR mutations are also found in lung adenocarcinoma tumor specimens from men and people who smoked cigarettes.[15]

The rapid and dramatic clinical responses to EGFR TKI therapy seen in patients with *EGFR* gene mutations led to the "oncogene addiction" hypothesis,[16,17] which states that because EGFR mutant lung cancers develop in a setting in which the mutated receptor is constantly transducing high levels of antiapoptotic signals, the cancer cells are "addicted" to EGFR kinase prosurvival signaling. As a result, sudden interruption of EGFR signaling by EGFR TKIs causes massive cell death. Another hypothesis, termed the "oncogenic shock" hypothesis,[18] states that proapoptotic signals are still present in EGFR mutant lung cancer cells. When receptor signaling is inhibited by EGFR TKIs, both antiapoptotic and proapoptotic signals are blocked. However, antiapoptotic signals decay much more rapidly than proapoptotic signals, leading to a temporary predominance in proapoptotic signaling and cell death.

A large number of retrospective series have demonstrated that the response rate of *EGFR* mutation–positive patients to EGFR TKIs exceeds 60%,[4] which is markedly higher than the typical 20% response rate to combination chemotherapy in NSCLC.[19] Several studies have also shown that NSCLC patients harboring *EGFR* mutations survive longer with EGFR TKI therapy compared to NSCLC patients with wild type EGFR treated with TKIs. Thus, personalized therapy targeting the specific genetic changes in a patient's lung cancer is critical for improving response rates and overall survival (OS).

Several randomized phase 3 trials comparing the first-generation EGFR TKI gefitinib to platinum-based chemotherapy in patients with advanced NSCLC have been reported. Although participants were not selected based on *EGFR* gene mutation status, the IPASS trial enriched its study population for subjects with *EGFR* mutations by selecting patients according to clinical factors known to be associated with higher prevalence of *EGFR* mutation: East Asian patients, adenocarcinomas, and never-smokers or former light smokers.[20] The IPASS trial was designed with progression-free survival (PFS) as the primary endpoint to assess the noninferiority of gefitinib compared with carboplatin/paclitaxel. The study met its primary objective demonstrating noninferiority and showed superiority of gefitinib for PFS, objective response rate (ORR), and quality of life for the entire cohort. However, results depended upon the *EGFR* mutation status. For patients whose tumors contained an *EGFR* mutation, PFS was significantly prolonged with gefitinib (9.5 months) in contrast to carboplatin/paclitaxel (6.3 months). In comparison, for those without an *EGFR* mutation, PFS was significantly shorter with gefitinib (1.5 months vs. 6.5 months). Two additional randomized phase 3 trials of patients with advanced NSCLC selected for *EGFR* mutations (either the exon 19 deletion or L858R point mutation) also demonstrated a significant increase in PFS with gefitinib compared to platinum-based chemotherapy as first-line treatment.[21,22] Similarly, a multicenter, open-label, randomized, phase 3 trial of the first-generation EGFR TKI erlotinib versus standard chemotherapy as first-line treatment for Caucasian patients with advanced-stage *EGFR* mutation–positive NSCLC (EURTAC) reported a median PFS of 9.7 months in the erlotinib group, compared with 5.2 months in the standard chemotherapy group.[23] These studies confirm that treatment of *EGFR* mutation–positive patients with first-line EGFR TKI therapy is superior to standard chemotherapy and represents one of the most promising advances in the field of lung cancer.

Unfortunately, virtually all patients who initially respond to EGFR TKI therapy will develop resistance and suffer a clinical relapse. Approximately 50% of the cases of acquired TKI resistance are attributed to a secondary *EGFR* gene mutation, the threonine-to-methionine point mutation at amino acid 790 (T790M) in exon 20 (Fig. 107-3).[24] The threonine residue at position 790 is highly conserved across the oncogenic RTKs EGFR, ABL, and KIT, and mutations of this residue often lead to resistance to kinase-targeted drugs.[25] Threonine 790 is in a key location at the entrance to a hydrophobic pocket at the back of the ATP-binding cleft. Mutation to a bulkier methionine group, the T790M "gatekeeper" mutation, leads to drug resistance by increasing the receptor's affinity for ATP at the ATP-binding pocket, allowing ATP to outcompete a TKI for the binding site, thereby minimizing the effects of the TKI.

Second-generation EGFR TKIs, such as afatinib and dacomitinib, were developed with a specific focus on overcoming resistance to first-generation EGFR TKIs induced by the T790M mutation. These second-generation EGFR TKIs are small molecules that covalently bind to the intracellular kinase domain of the EGFR protein. In addition to binding irreversibly to wild-type EGFR, HER2, and HER4, these novel agents also bind to EGFR carrying the T790M mutation. A phase 3 study comparing afatinib versus cisplatin plus pemetrexed in patients with metastatic lung adenocarcinoma with EGFR mutations demonstrated superior median PFS in the afatinib group compared to the cisplatin plus pemetrexed group (11.1 vs. 6.9 months; hazard ratio [HR], 0.58; $p = 0.001$).[26] A randomized, open-label, phase 2b trial (LUX-Lung 7) comparing afatinib to gefitinib for the first-line treatment of patients with advanced-stage EGFR mutation–positive NSCLC found afatinib treatment was associated with significantly improved PFS (median 11.0 vs. 10.9 months; HR, 0.73; $p = 0.017$) and time to treatment failure (median 13.7 vs, 11.5 months; HR, 0.73; $p = 0.0073$).[27] A randomized, open-label, phase 3 study of dacomitinib versus gefitinib as first-line treatment for patients with *EGFR* mutation–positive, advanced-stage NSCLC (ARCHER 1050) showed median PFS was 14.7 months in the dacomitinib group and 9.2 months in the gefitinib group (HR, 0.59; $p < 0.0001$).[28] Dacomitinib also showed significant improvement in OS over gefitinib (34.1 vs. 26.8 months; HR, 0.76; $p = 0.044$).[29] Thus, second-generation EGFR TKIs appear to be superior to platinum-based chemotherapy and first-generation EGFR TKIs for the treatment of *EGFR* mutation–positive NSCLC.

Although second-generation EGFR TKIs showed significant improvement in PFS, a phase 2b/3 randomized trial (LUX-Lung 1) evaluating afatinib in patients with advanced-stage lung adenocarcinoma with previous treatment failure on first-generation EGFR TKIs (likely due to the EGFR T790M mutation) failed to show improvement in OS.[30] As a result, third-generation EGFR TKIs were developed to further overcome T790M-mediated EGFR TKI resistance. Osimertinib is an oral, third-generation, irreversible EGFR TKI that selectively inhibits mutant EGFR proteins, with lower activity against wild-type EGFR. In a double-blind, phase 3 trial of patients with previously untreated, *EGFR* mutation–positive, advanced-stage NSCLC (FLAURA), median PFS was significantly longer with osimertinib than with first-generation EGFR TKIs (18.9 vs. 10.2 months; HR, 0.46; $p < 0.001$).[12] Median OS was 38.6 months in the osimertinib group and 31.8 months in the first-generation EGFR TKI group (HR, 0.80; $p = 0.046$).[31] A randomized, international, open-label, phase 3 trial compared osimertinib to platinum-based therapy plus pemetrexed in patients with T790M-positive advanced NSCLC who had disease progression after first-line EGFR TKI therapy (AURA3).[32] Median PFS was significantly longer with osimertinib than with platinum therapy plus pemetrexed (10.1 vs. 4.4 months; HR, 0.30; $p < 0.001$). As a result of these studies, osimertinib has become the standard of care for the first-line treatment of advanced *EGFR* mutation–positive NSCLC as well as for EGFR T790M-positive NSCLC. Despite its strong therapeutic effects, osimertinib-treated patients are still prone to developing resistance. Studies are being performed analyzing the effects of combining osimertinib with gefitinib to combat acquired resistance.

ROS1

ROS1 encodes an integral membrane protein RTK and was identified as a potential oncogene in NSCLC in 2007.[6] Chromosomal rearrangements result in gene fusions involving the 3' region of *ROS1*, which encompasses the kinase domain, and several different 5' fusion partners, including *CD74*, *EZR*, *SLC24A2*, and *FIG*.[33,34] ROS1 fusions lead to constitutive TK activation and resultant stimulation of the PI3K/AKT/mTOR, JAK/STAT, and RAF/MEK/ERK signaling pathways, which promote cell survival and proliferation. *ROS1* gene fusions account for 1% to 2% of NSCLC cases. Clinical characteristics of NSCLC patients with ROS1 gene fusions are similar to patients with EGFR mutation–positive NSCLC: Asian ethnicity, young age (median 49.8 years), never-smokers, and adenocarcinoma histology. *ROS1* gene fusions appear mutually exclusive of other known oncogenic drivers.

The TK domains of ALK and ROS1 share 77% amino acid identity within the ATP-binding sites.[35] This led investigators to treat advanced NSCLC patients who tested positive for *ROS1* rearrangements with the ALK inhibitor crizotinib.[35,36] Crizotinib showed marked antitumor activity in patients with advanced-stage *ROS1*-rearranged NSCLC, yielding an objective response rate of 72% and median PFS of 19.2 months.[35] Based on these results, the U.S. FDA approved crizotinib for the management of *ROS1*-rearranged locally advanced or metastatic NSCLC in 2016.

Despite successful outcomes, secondary mutations in *ROS1* can lead to acquired resistance in NSCLC patients treated with crizotinib. In addition, crizotinib's limited blood–brain barrier penetration may lead to a high incidence of CNS recurrence. Entrectinib is a multikinase inhibitor with activity against ROS1 that was designed with the ability to cross the blood–brain barrier and be retained in the CNS to overcome this problem. In an integrated analysis of three phase 1–2 trials (ALKA-372-001, STARTRK-1, and STARTRK-2), 41 (77%) of 53 patients had a response to entrectinib. Of the 20 patients with baseline CNS metastases assessed by blind independent central review, 11 (55%) had an intracranial response to entrectinib.[37] Based on these clinical trial data, the U.S. FDA approved the use of entrectinib for the treatment of metastatic ROS1-positive NSCLC in the summer of 2019. A number of other drugs have shown activity against ROS1 in phase 1–2 clinical trials, including ceritinib, brigatinib, DS-6051b, lorlatinib, and repotrectinib. Ongoing studies are needed to determine whether these drugs can be used as first-line treatment or whether they are better used after progression following crizotinib therapy. Novel drugs with strong safety profiles and the ability to overcome resistance mutations will increase treatment options for ROS1-rearranged NSCLC patients.

MET

The MET pathway is activated in a number of human malignancies, including lung cancer. MET receptor overexpression by immunohistochemistry has been reported in NSCLCs, in particular lung adenocarcinomas.[38] Using fluorescence in situ hybridization (FISH), the Lung Cancer Mutation Consortium reported that 4.1% of lung adenocarcinomas have MET gene amplification.[39] MET gene mutations have also been reported in human lung cancer, mainly clustered in the juxtamembrane domain, which enhance oncogenic signaling, tumorigenicity, cell motility, and migration. MET kinase domain mutations are also somatically selected in metastatic tumors compared with the primary tumors. Among patients with NSCLC, MET exon 14 mutations occur in 3% to 4% and MET amplifications occur in 1% to 6%.[40–43]

In preclinical studies, small molecule MET inhibitors decrease cell viability and growth, and they induce apoptosis in NSCLC cells via inhibition of MET/hepatocyte growth factor (HGF) signaling. Multiple drugs are being tested for clinical activity against *MET*-dysregulated NSCLC. A retrospective analysis using data from 12 institutions found that median OS for patients with *MET* exon 14 mutant NSCLC who were treated with a MET TKI was significantly improved compared to patients who never received a MET TKI (24.6 vs. 8.1 months).[44] A multiple cohort, phase 2 study evaluated the selective MET inhibitor capmatinib in patients with *MET* exon 14–mutated or *MET*-amplified advanced-stage NSCLC and found that ORR was 41% in pretreated patients and 68% in untreated patients.[45] The efficacy in *MET*-amplified NSCLC was higher in tumors with a gene copy number of 10 or higher than in those with low gene copy number. Tepotinib is a highly selective oral MET inhibitor that has shown promising clinical activity in patients with MET-driven tumors. In an open-label, phase 2 study in patients with advanced or metastatic NSCLC with a confirmed *MET* exon 14 mutation, the use of tepotinib was associated with a partial response in 46% of patients.[46] These trial data have led to U.S. FDA approval of capmatinib and tepotinib for advanced-stage NSCLCs containing *MET* exon 14 mutations. Other MET inhibitors under active clinical evaluation include the small molecule MET inhibitors savolitinib and cabozantinib.

RET

REarranged during Transfection (RET) is a transmembrane RTK with oncogenic characteristics and the ability to signal the PI3K/AKT, JNK, and RAS/MAPK and RAS/ERK pathways. Gene rearrangements in *RET* can lead to chimeric genes derived from the RET 3’ sequences encoding the intracellular TK domain and the 5’ sequences from another gene. These RET fusion proteins lead to a constitutively active receptor, ligand-independent signaling, and lung tumorigenesis. Several different fusion partners have been described in NSCLC.[47] Genetic rearrangements and translocations in *RET* have been identified in 1% to 2% of all lung cancers, with a higher incidence in never-smokers, females, adenocarcinoma, and poorly differentiated tumors.[48–51] Multitargeted kinase inhibitors that exhibit some degree of RET inhibition have been evaluated in prospective clinical trials.[52–55] But the use of these drugs resulted in limited clinical benefit and dose-limiting off-target toxic effects.[56,57]

Selpercatinib is a novel, ATP-competitive, highly selective small molecule inhibitor of RET kinase. The efficacy of selpercatinib was evaluated in a phase 1–2 clinical trial of patients with *RET* fusion–positive advanced-stage NSCLC (LIBRETTO-001).[58] Among patients who had previously received platinum-based chemotherapy (median of three previous systemic therapy regimens; 55% had received previous immunotherapy), 64% of the patients who received selpercatinib had an objective response. Among previously untreated patients, the percentage who had a response was even higher at 85%. Another selective RET inhibitor that is currently under investigation in advanced NSCLC is pralsetinib. These selective RET inhibitors may soon become part of the arsenal of targeted therapies available for the treatment of NSCLC.

HER2

Human epidermal growth factor receptor 2 (HER2, also known as ERBB2) is a member of the EGFR family of RTKs. HER2 has been studied extensively in breast cancer, where HER2 gene amplification has important implications for treatment with targeted therapy and prognosis. *HER2* gene amplification, HER2 protein overexpression, and *HER2*-activating kinase domain mutations also have been reported in NSCLC. Following successes in targeting HER2 in breast cancer, the monoclonal antibody trastuzumab was tested in HER2-overexpressing NSCLC. However, multiple clinical trials investigating the use of trastuzumab-based chemotherapy met with disappointing results.[59–62] The HER2 antibody–drug conjugate trastuzumab emtansine (T-DM1) also had limited therapeutic efficacy in HER2-overexpressing NSCLCs.[63,64] Thus, HER2 protein overexpression may not represent a valuable therapeutic target in advanced NSCLC. However, there is no consensus regarding how to score and classify HER2 protein overexpression in lung cancer. Two different scoring methods exist to classify HER2 protein expression: an IHC scoring system ranging between 0 and 3+, and the H-score, which is a semiquantitative assessment performed by multiplying staining intensity with the percentage of positive tumor cells. Low concordance in HER2 expression assessment by pathologists may also contribute to heterogeneous study populations.

In contrast to HER2 overexpression, targeting *HER2* mutations in NSCLC may have more therapeutic potential. Mutations within the kinase domain of *HER2* were first described in lung cancer in 2004 and occur in 1% to 3% of NSCLCs.[65] As expected, since HER2 is in the EGFR family of RTKs, clinical characteristics of NSCLC patients with *HER2* mutations are similar to those seen with EGFR mutations, including Asian ethnicity, female sex, never-smoker status, adenocarcinoma histology, and high morphologic grade. *HER2* mutations appear to be mutually exclusive of other oncogenic driver mutations, although some may be acquired as a resistance mechanism to TKIs as in EGFR mutation–positive NSCLC. Various therapeutic strategies have been developed to target *HER2*-mutated NSCLCs and have met with variable success. Pan-HER inhibitors (e.g., afatinib, neratinib, dacomitinib) have modest activity in NSCLC patients with *HER2* mutations (ORR, 0%–19%; median PFS, 2.9–5.5 months).[66–71] In contrast, trastuzumab and T-DM1 have been associated with improved outcomes, with ORR ranging between 14.8 and 50.9% and median PFS of 4.8 to 5.5 months.[64,67,72,73] Novel pan-HER inhibitors have demonstrated antitumor activity in NSCLC preclinical models and early clinical studies,[74,75] and are currently under evaluation in multiple clinical trials.

Intracellular Signaling Pathways and Targets

Various intracellular signaling pathways are activated in NSCLC and can be targeted therapeutically (Fig. 107-2A). Downstream of membrane bound RTKs is the RAS/mitogen-activated protein kinase (MAPK) pathway, which is a pivotal intracellular signaling pathway that transmits RTK signals to the nucleus via a cascade of specific protein phosphorylation events. In addition to RTKs, the MAPK pathway can also be activated by oncogenic driver mutations that lead to constitutive TK signaling, such as *EML4-ALK* rearrangements. In this section, we provide an overview of the roles of these signaling pathways and discuss how various components of these pathways are being considered as targets for lung cancer treatment.

Anaplastic Lymphoma Kinase Rearrangements

ALK is a member of the insulin receptor TK superfamily. In 2007, Soda et al. reported a new molecular abnormality involving the fusion of ALK with EML4 in lung adenocarcinoma.[5] The fusion protein results from an inversion in the short arm of chromosome 2 that fuses the N-terminal domain of *EML4* to the intracellular kinase domain of *ALK*, leading to constitutive activation of the ALK kinase, promoting cell proliferation and survival (Fig. 107-4). In the original report by Soda et al., 6.7% of unselected NSCLC patients had the EML4-ALK fusion protein. More than seven ALK rearrangements have been identified involving various EML4-ALK breakpoints, and rarely, other non-EML4 fusion partners. Similar to the clinical phenotype seen in patients with *EGFR* mutations, *ALK* rearrangements occur more commonly in younger patients who are never or former smokers and are predominantly associated with adenocarcinoma. However, patients with *ALK* rearrangements have characteristics that distinguish them from patients with *EGFR* mutations. EML4-ALK positive patients are younger than patients with *EGFR* mutations, with a median age of 52 years compared to 66 years.[36,76] Most reports show that *ALK* rearrangements are mutually exclusive of *EGFR* and *KRAS* mutations.

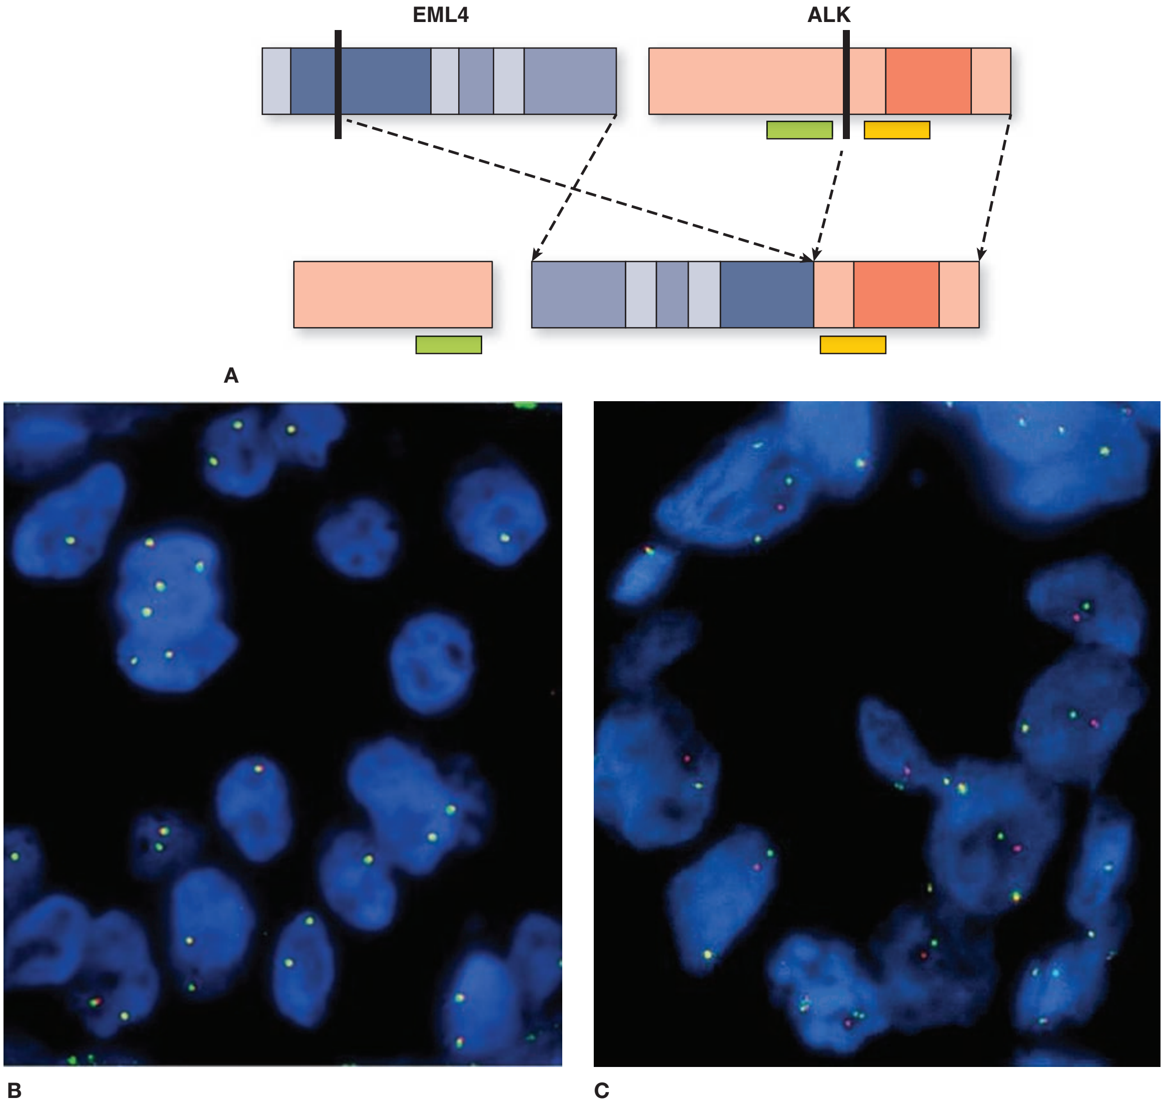

Figure 107-4 Schematic of echinoderm microtubule-associated protein-like 4 (EML4) translocation to the anaplastic lymphoma kinase (ALK) and its detection by fluorescence in situ hybridization (FISH). Both *EML4 (blue)* and *ALK (red)* genes are located on the short arm of chromosome 2 (**A**). A chromosomal inversion leads to *EML4-ALK* rearrangement and generation of a fusion protein. Green and orange bars represent DNA probes corresponding to the 5′ and 3′ fragments of the *ALK* gene. FISH detection of *EML4-ALK* rearrangement uses break-apart technology (ALK Break Apart FISH Probe, Abbott Molecular), which detects the adjacently located *EML4* and *ALK* genes in wild-type signals (**B**, *adjacent green-orange probes*) and break-apart signals caused by chromosomal inversion (**C**, *separated green-orange*). (***B** and **C:** FISH images reproduced with permission from Dr. Marileila Garcia, University of Colorado Anschutz Medical Campus.)*

In preclinical studies, the ALK kinase inhibitor TAE684 was shown to inhibit the growth of an EML4-ALK containing NSCLC cell line, both in vitro and in vivo.[5,77–80] These findings led to the testing of crizotinib, a small molecule competitive inhibitor targeted to the ATP-binding pocket of the ALK tyrosine kinase. A phase 1 study of patients with EML4-ALK–positive stage III or IV NSCLC treated with crizotinib demonstrated an overall response rate of 60.8%, including three complete responses.[36] Median time to first documented objective response was 7.9 weeks. Median PFS was 9.7 months, and estimated OS at 6 and 12 months was 87.9% and 74.8%, respectively. Based on these responses, in 2011 the U.S. FDA granted approval for crizotinib as the first ALK inhibitor for use in ALK rearrangement–positive NSCLC patients. A phase 2 study confirmed the efficacy of crizotinib in 1066 ALK rearrangement–positive NSCLC patients when used in a second-line setting.[81] In a subgroup of patients who had ALK status determined by a central laboratory using break-apart FISH (n = 908), ORR was 54%, with a median PFS of 8.4 months and a median OS of 21.8 months. Afterward, two phase 3 studies proved that targeted therapy with crizotinib in ALK rearrangement–positive NSCLC patients is superior to standard chemotherapy regimens in both first-line and second-line treatment settings.[82,83] These data show convincingly that ALK inhibition is effective in patients with NSCLC carrying an *ALK* rearrangement.

Similar to EGFR targeted therapy, resistance to crizotinib in EML4-ALK–positive NSCLC has been reported. A patient in the original phase 1 study of crizotinib developed resistance after 5 months of therapy.[84] Deep sequencing of complementary DNA comparing *EML4-ALK* translocation before and after resistance identified two independent events in the resistant cancers: point mutation of residue 1156 from cytosine to tyrosine (C1156Y), and, at residue 1196, from leucine to methionine (L1196M). In vitro, these new mutations decreased the fusion protein's sensitivity to crizotinib. Structural analysis of these mutants showed that C1156Y was close to the edge of the ATP-binding pocket. Interestingly, L1196M corresponds to the T790M gatekeeper mutation in EGFR, suggesting a common mechanism for the development of resistance in tyrosine kinases. Analysis of tissue obtained from patients with *ALK* gene–rearranged NSCLC who showed radiologic progression while on crizotinib found multiple mechanisms of resistance to crizotinib: secondary mutations in the TK domain of *ALK*, new-onset *ALK* copy number gain, and outgrowth of either *EGFR* or *KRAS* mutant NSCLC.[85]

The identification of mutations that lead to primary and secondary resistance to crizotinib fueled the development of second-generation ALK inhibitors. Ceritinib is a second-generation oral ALK inhibitor, which has been shown to overcome *ALK* mutations that lead to acquired resistance to crizotinib. In a randomized, controlled, open-label, phase 3 trial, patients with *ALK*-rearranged advanced-stage NSCLC who had received previous chemotherapy and crizotinib were randomized to ceritinib or chemotherapy (pemetrexed or docetaxel).[86] Ceritinib showed a significant improvement in median PFS compared with chemotherapy (5.4 vs. 1.6 months; HR, 0.49; p <0.001), indicating that ALK-positive NSCLC patients benefit from ceritinib after failure of crizotinib. However, no randomized clinical studies have directly compared ceritinib and crizotinib head to head. Another second-generation ALK inhibitor that has demonstrated efficacy against crizotinib-resistant mutations is alectinib. In a cohort of patients with advanced *ALK*-positive NSCLC who had progressed after crizotinib, treatment with alectinib led to an ORR of 48% and a median PFS of 8.1 months.[87] Later, several phase 3 clinical trials were conducted comparing alectinib with crizotinib in treatment-naïve patients with ALK-positive NSCLC.[88–90] Median PFS was significantly longer with alectinib than with crizotinib, leading to alectinib being recognized as a better first-line treatment option than crizotinib in several lung cancer treatment guidelines.[91–93] The second-generation ALK inhibitor brigatinib also has been compared to crizotinib in the first-line setting in ALK-positive NSCLC patients. Compared to crizotinib, brigatinib showed superiority in median PFS (24.0 vs. 11.0 months; HR, 0.49; p <0.0001), leading to the U.S. FDA approving brigatinib for the first-line treatment of patients with ALK-positive metastatic NSCLC.

Unfortunately, ALK-positive NSCLC still develops resistance to second-generation ALK inhibitors. As a result, lorlatinib, a third-generation ALK inhibitor, was designed to target mutations that drive resistance to crizotinib and second-generation ALK TKIs. Lorlatinib was also developed to cross the blood–brain barrier and facilitate CNS penetration. In a phase 2 study of patients with ALK-positive, advanced NSCLC with or without CNS metastases, lorlatinib showed substantial overall and intracranial activity, both in treatment-naïve patients and in those who had progressed on crizotinib or second-generation ALK TKIs.[94] Thus, lorlatinib represents a valid and powerful treatment strategy in heavily pretreated ALK-rearranged NSCLC patients.

RAS/MAPK Pathway

The MAPK pathway is one of the most extensively studied intracellular signaling pathways. The MAPK pathway modulates transcription factors, which in turn regulate gene expression in response to extracellular signals. In healthy cells, the MAPK signaling cascade mediates cellular growth, proliferation, and survival processes. Dysregulation of MAPK signaling in cancer is associated with evasion of apoptosis, uncontrolled cell proliferation, and resistance to chemotherapy and targeted therapies.

The MAPK pathway can be activated by multiple mechanisms, including activation of RTKs (e.g., EGFR, ROS1) in response to extracellular stimuli and mutations that lead to constitutive TK activity (e.g., EGFR mutations, *EML4-ALK* rearrangements). The canonic MAPK cascade is composed of three successive serine/threonine kinases: RAF, MEK, and ERK. Due to the alteration of the RAS/MAPK pathway in lung cancer, components of the pathway are considered to be promising drug targets for cancer therapies.

RAS

The *RAS* family of oncogenes includes neuroblastoma RAS viral oncogene homolog (*NRAS*), *KRAS*, and Harvey rat sarcoma viral oncogene homolog (*HRAS*). *KRAS* is the gene that is most commonly involved in lung cancer. *RAS* genes encode a family of membrane-bound guanine triphosphatases (GTPases or G proteins) whose signaling regulates cell growth, differentiation, and apoptosis. Similar to RTKs, G proteins can be thought of as "on/off switches" for signaling (Fig. 107-5). While in the "on" state, RAS is bound to guanosine triphosphate (GTP). A phosphate group is then transferred from GTP to a RAS effector molecule, activating the downstream signaling process. The remaining guanosine diphosphate (GDP) form of the complex is incapable of signaling and puts the RAS complex in an "off" state. Activation and inactivation of RAS and other small G proteins are thus controlled by cycling between the active GTP-bound and inactive GDP-bound forms. Activated RAS stimulates RAF protein kinases, which in turn initiates the MEK cascade leading to ERK activation and ultimately activation of transcription factors that regulate cell cycle progression. Other effectors of activated RAS include signal transducer and activator of transcription (STAT) and PI3K signaling cascades.

In 1984, a human lung cancer specimen was found to contain an activating *KRAS* mutation that was not found in corresponding normal tissue.[95] Subsequently, investigators have found that approximately 25% to 30% of NSCLCs harbor activating point mutations in *RAS* genes, with *KRAS* accounting for the majority

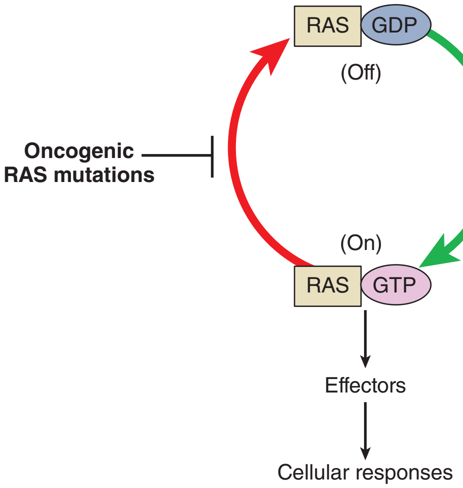

Figure 107-5 Activation cycle of RAS proteins. Growth factor stimulation leads to activation of RTKs, which causes the adaptor protein growth factor receptor–bound protein 2 (Grb2) to bind to RAS and recruit Son of Sevenless (SOS), which stimulates the conversion of RAS from the inactive guanosine diphosphate (GDP)-bound form to the active guanosine triphosphate (GTP)-bound form. Stimulation of RAS activates a mitogen-activated protein kinase cascade, leading to cell growth and differentiation. Oncogenic RAS mutations result in compromised GTPase activity, causing mutant RAS to favor its active GTP-bound state. Therefore, mutant RAS results in continuous signaling even in the absence of growth factor stimulation, conferring a proliferative advantage to tumor cells.

of *RAS* mutations (90%),[96] specifically in codons 12, 13, and 61.[97] In NSCLC, the most frequent KRAS mutations are G12C (~50%), followed by G12V and G12D.[98,99] These mutations result in compromised GTPase activity, causing mutant RAS protein to favor its active GTP-bound state. Therefore, mutant RAS protein results in continuous signaling even in the absence of growth factor stimulation, conferring a proliferative advantage to tumor cells.

Although *KRAS* mutations are the most common oncogenic driver in lung adenocarcinomas, *KRAS* mutations are uncommon in lung squamous cell carcinomas. In contrast to oncogenic driver mutations in RTKs, *KRAS* mutations are more common in NSCLC tumors from smokers than from never-smokers. A meta-analysis of 53 studies of lung cancer assessing the prognostic value of *RAS* mutations on survival found a worse survival for NSCLC with *KRAS* mutations compared to non-KRAS-mutant NSCLC, particularly in adenocarcinomas.[100] Because the RAS protein is a downstream effector of EGFR and other RTKs, *KRAS* mutations have been assessed as a primary mechanism of resistance to EGFR TKIs, and the presence of a *KRAS* mutation may predict that a patient will not respond to EGFR TKIs.

Due to the frequency of *KRAS* mutations in NSCLC, development of agents to inhibit mutated RAS proteins has been widely pursued. However, the search for RAS inhibitors has proved challenging and for decades KRAS was considered undruggable. Whereas RAS binds GTP with picomolar affinities, the concentration of GTP in cells approaches micromolar levels. Thus, targeting mutant GTP-bound RAS with nucleotide analogues has been unsuccessful due to the inability to compete with the high GTP levels. Considerable research went into the development of farnesyl transferase inhibitors to alter RAS membrane localization such as farnesylthiosalicylic acid (salirasib), which mimics the carboxy terminal amino acid of RAS and dislodges activated RAS from the membrane. However, farnesyl transferase inhibitors failed to demonstrate efficacy in clinical trials against tumors containing mutant KRAS,[101] likely due to alternate pathways for farnesyl modification of KRAS. Attempts to block RAF, one of the major downstream effectors of RAS, led to the unexpected discovery that in RAS-transformed cells, RAF inhibitors activate the MAPK pathway instead of inhibiting it.[102]

Recent breakthroughs may pave the way to developing specific therapies targeting mutant KRAS proteins. In 2013, Shokat et al. identified electrophilic compounds that interact selectively with the GDP form of oncogenic KRAS^{G12C} protein and bind covalently to a previously unknown allosteric pocket under the switch II loop region (S-IIP) near the guanosine nucleotide binding site.[103] These findings led to the discovery of the novel covalent KRAS^{G12C} inhibitor ARS-1620,[104–106] which binds covalently to the S-IIP pocket and makes KRAS^{G12C} preferentially accept GDP instead of GTP, reducing GTP-bound KRAS^{G12C} by more than 90% and locking KRAS^{G12C} in the GDP-bound off state. Importantly, ARS-1620 binds specifically to KRAS^{G12C} and has no effect on either wild-type KRAS or other mutant KRAS proteins. In preclinical patient-derived tumor models, ARS-1620 induced tumor regression, providing in vivo evidence that mutant KRAS^{G12C} can be selectively targeted.[105]

These findings have led to the development of several novel direct covalent KRAS^{G12C} inhibitors that are currently undergoing testing in clinical trials. Sotorasib (AMG 510) is a small molecule structurally related to ARS-1620, but it takes advantage of novel binding interactions with the S-IIP pocket, which improve its potency approximately 10-fold compared to ARS-1620.[107] In preclinical animal studies, treatment with sotorasib resulted in a proinflammatory tumor microenvironment and produced durable cures in combination with anti–PD-1 immune checkpoint inhibitors.[108] In a phase 1 trial of sotorasib in patients with advanced solid tumors harboring the *KRAS*^{G12C} mutation, 32.2% (19 patients) of NSCLC patients had a confirmed objective response and 88.1% (52 patients) had disease control, with median PFS of 6.3 months.[109] Another small molecule inhibitor that irreversibly binds to the KRAS^{G12C} S-IIP pocket and locks it in an inactive GDP-bound state is MRTX849.[110] In vitro, MRTX849 is a potent and selective inhibitor of KRAS^{G12C}-dependent signal transduction and cell viability. In vivo, treatment with MRTX849 inhibited KRAS signaling and induced tumor regression in multiple KRAS^{G12C} cell line and patient-derived xenograft models, and MRTX849 (adagrasib) has also advanced to clinical trials.[111] The revolutionary strategy to use covalent allosteric inhibitors that target the S-IIP pocket has provided impetus for renewed drug development efforts and has paved the way for targeted agents to treat KRAS-mutant NSCLC. The US FDA has approved both sotorasib and adagrasib for patients with KRAS G12C-mutated NSCLC who have already received at least one prior systemic therapy.

RAF

The RAF family of serine/threonine kinases, which includes ARAF, BRAF, and RAF-1 (also known as CRAF), plays a critical role in cellular growth, proliferation, and differentiation through the MAPK signaling pathway. Although RAF is activated by RAS, activation can also occur independently of RAS through other activators such as Src, c-Jun NH2-terminal kinase, interferon β, and protein kinase C-α (PKC-α), or through dimerization between RAF isoforms. In NSCLC, activating mutations of the *BRAF* gene have been reported in 3% to 5% of NSCLC tumors, most of which are adenocarcinoma.[112,113] Similar to other oncogenes, driver mutations in *BRAF* are mutually exclusive of *EGFR* mutations or *ALK* rearrangements. BRAF^{V600E} represents the most frequent BRAF mutation in lung cancer, accounting for approximately 50% of BRAF-mutant NSCLC.[114] Whereas BRAF^{V600E} mutations arise more frequently in women and are not correlated to smoking history, non-V600E BRAF mutations have been reported to be more frequent in male patients with a history of smoking.[113] BRAF^{V600E} mutations lead to constitutive activation, initiating the MAPK signaling cascade without activation by RAS, resulting in uncontrolled cellular proliferation and lung carcinogenesis.

MEK

MEK1 and MEK2 are closely related, dual-specificity tyrosine/threonine protein kinases in the MAPK signaling pathway that transmit mitogenic signals from outside the cell to the nucleus through multistage phosphorylation. MEK plays an important role in cell proliferation, differentiation, apoptosis, and stress responses. MEK1/2 have a unique pocket structure adjacent to the ATP-binding site that is an ideal target for small molecule agents.[115] The presence of small molecule inhibitors induces several conformational changes in the unphosphorylated MEK1 and MEK2 proteins that lock them into an inactive state. As MEK1/2 are the downstream effectors of RAS and RAF, MEK inhibitors have been developed as a strategy to treat NSCLC patients with *KRAS* or *BRAF* mutations. To date, four MEK inhibitors have been approved by the U.S. FDA: trametinib, binimetinib, selumetinib, and cobimetinib. Several phase 2 trials have investigated MEK inhibitors for the treatment of patients with advanced-stage NSCLC.[116–119] Unfortunately, these studies found that monotherapy with MEK inhibitors resulted in poor clinical outcomes and more toxicity for NSCLC patients compared with conventional chemotherapy.

Although MEK inhibitor monotherapy has been ineffective for NSCLC patients, the combination of MEK and BRAF inhibitors was evaluated in a phase 2, multicenter, nonrandomized, open-label, single-arm study. Patients with pretreated metastatic $BRAF^{V600E}$-mutant NSCLC treated with the combination of the oral RAF inhibitor dabrafenib and the oral MEK1/2 inhibitor trametinib had an ORR of 63.2% and median PFS of 9.7 months.[120] Similarly, in a phase 2, multicenter, nonrandomized, open-label, single-arm study, patients with previously untreated metastatic $BRAF^{V600E}$-mutant NSCLC treated with oral dabrafenib and oral trametinib had an ORR of 64% and median PFS of 10.9 months.[121] Based on these data, the U.S. FDA expanded indications for dabrafenib and trametinib to include the treatment of patients with metastatic NSCLC harboring $BRAF^{V600E}$ mutations.

ERK

ERK1 and ERK2 are structurally similar isoforms of ERK that are important effectors in the MAPK pathway. ERK is activated by its upstream effector MEK through phosphorylation. In the cytoplasm, ERK modulates key cytoskeletal proteins that affect motility, metabolism, and cell adhesion. Upon activation, ERK dimerizes and localizes to the nucleus, where it phosphorylates and activates several transcription factors that are involved in cell proliferation and survival. Although BRAF/MEK inhibitor combination therapy provides significant additional benefit beyond monotherapy, patients eventually develop resistance and disease progression. Several mechanisms of resistance have been identified, which typically lead to reactivation of ERK signaling and escape of tumor cells from combination BRAF/MEK inhibitor therapies.[122,123] Due to its aberrant expression in several cancers, including NSCLC, ERK is being studied as a potential therapeutic target in cancers with *BRAF*, *RAS*, or *MEK* mutations. Moreover, as the most distal master kinase of the MAPK signaling pathway, ERK inhibition may avoid or overcome resistance mechanisms that arise in upstream kinases.

Ulixertinib is a highly potent, selective ERK1/2 kinase inhibitor that has been shown to reduce tumor growth and induce tumor regression in *BRAF*- and *RAS*-mutant xenograft models. An open-label, dose-escalation study of oral ulixertinib was undertaken in solid tumor patients with *BRAF*, *RAS*, and *MEK* mutations.[124] In patients with *BRAF*-mutant NSCLC, partial responses were seen in 3 of 12 evaluable patients (2 with $BRAF^{V600E}$ mutations and 1 with non-V600E). Of note, CNS responses were seen in a patient with $BRAF^{V600E}$-mutant lung cancer with brain metastases. Due to concerns that ERK inhibitor monotherapy is likely to confer drug-acquired resistance, additional studies investigating ERK inhibitors in combination with TKIs or MEK inhibitors are currently being undertaken.

IMMUNOTHERAPY

The concept of mobilizing the host's immune system to treat cancer has been considered for decades. This approach represents a significant departure from chemotherapy-based cancer treatment, which targets the tumor through focusing on the host's own immune system to identify and kill cancer cells. However, therapeutically harnessing the immune system through cytokine therapy, vaccines, or interferons had limited success as a clear understanding of the tumor immune response was lacking. This changed with the discovery that the T-cell immune response is regulated not only by activation signals, but also by a plethora of inhibitory pathways called immune checkpoints, which inhibit the T-cell response and protect the host from damaging immune responses. Thus, T cell–mediated immunity consists of not only T-cell activation and proliferation, but also counterbalancing inhibitory pathways to control and ultimately abrogate T-cell effector functions. This discovery made possible the development of immune checkpoint inhibitors for cancer therapy. These drugs represent a departure in our pharmacologic approach to cancer therapy, as immune checkpoint inhibitors do not directly target tumor cells. Instead, they target the pathways that inhibit T-cell responses and enhance endogenous antitumor activity.

■ Immune Checkpoint Pathways

Immune checkpoints refer to inhibitory pathways in T cells crucial for maintaining self-tolerance. Tumors can also use these immune checkpoint pathways to inhibit T-cell response and escape immune surveillance. There are numerous immune checkpoints, and the two immune checkpoint receptors that have been most actively studied in the context of clinical cancer immunotherapy are cytotoxic T lymphocyte–associated protein 4 (CTLA-4) and programmed cell death receptor 1 (PD-1) (Fig. 107-2B). CTLA-4 regulates the amplitude of the early stages of T-cell activation by competing with the T cell CD28 receptor, whose signaling is required (co-stimulation) along with T-cell antigen receptor signaling for T-cell activation. The specific signaling pathways by which CTLA-4 blocks T-cell activation are still under investigation. Although CTLA-4 is expressed by activated CD8+ effector T cells, the major physiologic role of CTLA-4 appears to be through downmodulation of helper T-cell activity and enhancement of regulatory T (Treg) cell immunosuppressive activity. CTLA-4 blockade results in a broad enhancement of immune responses that are dependent on helper T cells and suppression of Tregs. Although currently approved only for the treatment of melanoma as monotherapy, CTLA-4 inhibitors are being investigated as treatment for a variety of cancer types, including NSCLC.

In contrast to CTLA-4, the major role of PD-1 is to interfere with signaling through the T-cell antigen receptor, acting later in the T-cell response by limiting the activity of T cells in peripheral tissues at the time of an inflammatory response (Fig. 107-6). PD-1 is expressed on tumor-infiltrating lymphocytes, and upon binding to its ligands PD-L1 and PD-L2, PD-1 inhibits kinases that are involved in T-cell activation. PD-1 is also highly expressed on Tregs and may enhance their proliferation. PD-1 ligand expression is frequently upregulated in human cancer, including NSCLC.[125] Inhibition of the PD-1 pathway has been shown to enhance intratumoral immune responses in preclinical studies, and blockade of PD-1 has introduced a new era in lung cancer treatment.

■ Pharmacologic Immune Checkpoint Inhibitors in Lung Cancer

Pharmacologic immune checkpoint inhibitors targeting PD-1, PD-L1, and CTLA-4 have been developed and tested in multiple

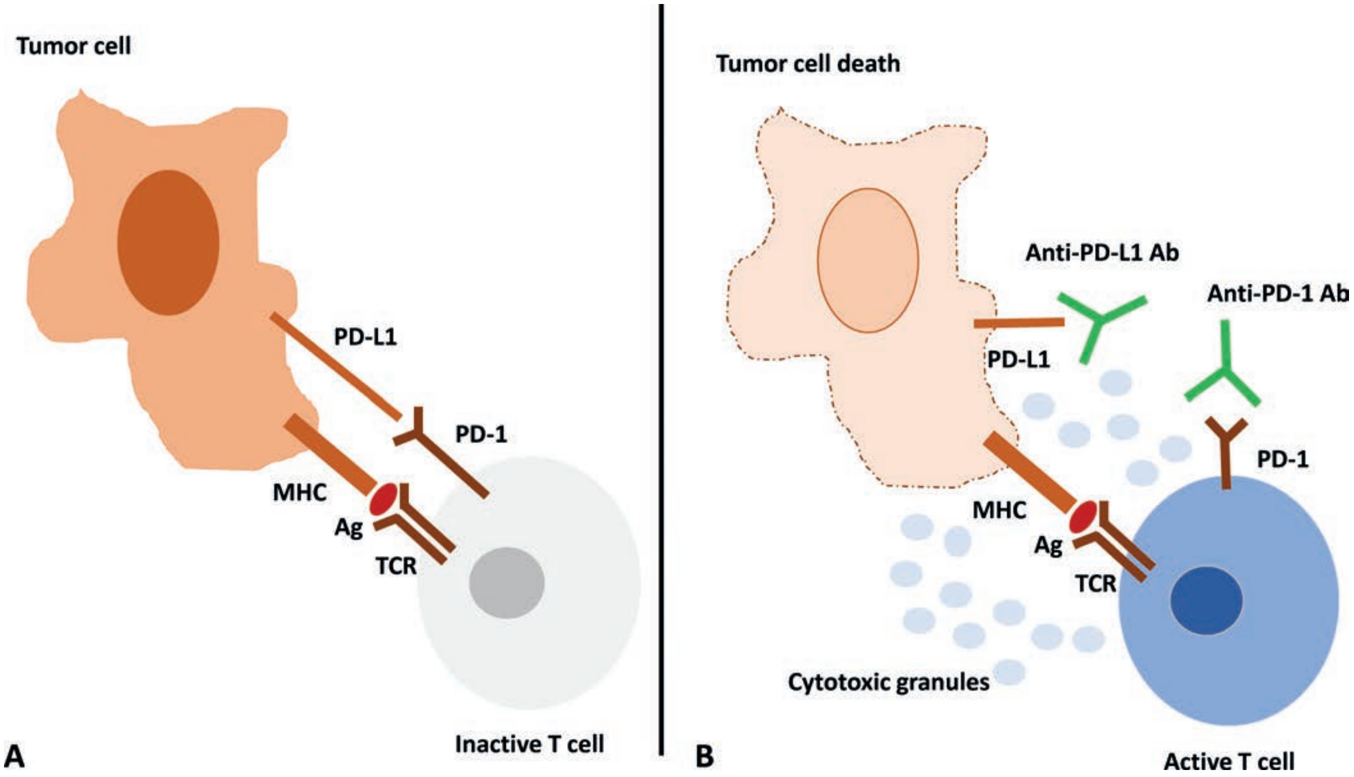

Figure 107-6 PD-1 and cancer. **A.** Ligation of T-cell PD-1 by tumor PD-L1 results in the downregulation of T-cell effector functions that destroy tumor tissue. **B.** Blockade of this pathway by anti–PD-1 or anti–PD-L1 antibodies prevents this downregulation and allows T cells to maintain their antitumor functionality and ability to mediate tumor cell death.

cancer types, including lung cancer. Whereas TKIs are typically effective only in patients with lung adenocarcinoma that express oncogenic driver mutations, immunotherapy with checkpoint inhibitors has been shown to be efficacious in both squamous and nonsquamous NSCLC patients, as well as a smaller proportion of SCLC patients. However, NSCLC patients with targetable driver mutations are unlikely to respond to immunotherapy as these cancers have a lower total mutational burden, resulting in fewer neoantigens seen by T cells.[126–128] Thus, precision targeted therapy and immunotherapy play distinct but complementary roles in the management of NSCLC.

PD-1/PD-L1 Inhibitors for NSCLC

Following successful clinical trials in the treatment of malignant melanoma, pharmacologic immune checkpoint inhibitors targeting the PD-1/PD-L1 pathway became established as a treatment for NSCLC patients. The initial trials and associated FDA-approved indications were in the second-line setting for stage IV squamous and nonsquamous NSCLC. The anti–PD-1 inhibitors nivolumab and pembrolizumab and the anti–PD-L1 inhibitor atezolizumab all showed significantly improved OS in previously treated, advanced-stage NSCLC compared with docetaxel.[129–132] Pembrolizumab and atezolizumab later proved to be superior to chemotherapy in the first-line setting for stage IV NSCLC patients with high PD-L1 expression,[133,134] and both pembrolizumab and atezolizumab have been approved by the U.S. FDA as monotherapy for the first-line treatment of PD-L1–positive metastatic NSCLC. Combinations of anti–PD-1 (pembrolizumab) or anti–PD-L1 (atezolizumab) inhibitors with platinum doublets demonstrated improved OS over chemotherapy alone[135–137] and have become standard of care for stage IV NSCLC patients without actionable oncogenic driver mutations. The PD-1 inhibitor durvalumab has also been approved by the U.S. FDA as adjuvant therapy after combined chemoradiotherapy in stage III NSCLC patients.[138]

Dual PD-1 and CTLA-4 Checkpoint Blockade for NSCLC

The combination of the anti–PD-1 inhibitor nivolumab and the anti–CTLA-4 inhibitor ipilimumab has been studied in NSCLC. CheckMate 227 included patients with previously untreated NSCLC and assigned treatment based on PD-L1 expression.[139] In the PD-L1–positive cohort, dual checkpoint blockade was superior to chemotherapy alone (median OS, 17.1 vs. 14.9 months; HR, 0.79). Dual PD-1 and CTLA-4 checkpoint blockade combined with chemotherapy as first-line treatment for NSCLC was explored in the phase 3 CheckMate 9LA trial.[140] This study included patients with treatment-naïve NSCLC, both squamous and nonsquamous, but excluded patients with *EGFR* mutations or *ALK* rearrangements. Patients were randomized to four cycles of chemotherapy alone or a combination of nivolumab, ipilimumab, and concurrent platinum-doublet chemotherapy for only two cycles. The combined chemoimmunotherapy approach improved OS, with a median OS of 15.6 months, compared to 10.9 months with chemotherapy alone (HR, 0.66). These studies led to U.S. FDA approval of nivolumab and ipilimumab as first-line treatment for patients with metastatic NSCLC with high PD-L1 tumor expression, and the approval of nivolumab plus ipilimumab and two cycles of platinum-doublet chemotherapy as first-line treatment for patients with metastatic or recurrent NSCLC.

PD-1/PD-L1 Inhibitors for SCLC

PD-1/PD-L1 inhibitors for SCLC can be considered with regard to their role in salvage chemotherapy and as part of first-line chemoimmunotherapy.

Salvage Immunotherapy In contrast with TKIs targeting oncogenic driver mutations, immunotherapy has also emerged as an effective treatment for extensive-stage SCLC. Initial efforts focused on the previously treated population. CheckMate 032 was a nonrandomized study that included 216 patients with SCLC.[141] Patients were treated with nivolumab alone or in combination with ipilimumab using various dosing schedules. Although nivolumab alone yielded an ORR of 10% and a relatively short median PFS of 1.4 months, a subset of patients achieved long-term survival with a 1-year OS rate of 33%. In the subset of patients who received nivolumab monotherapy as third-line treatment, the ORR was 11.9% with median OS of 5.6 months. While modest, the responses were durable with a median duration of response of 17.9 months and 18-month OS rate of 20%. As a result, nivolumab was granted accelerated approval by the U.S. FDA as third-line therapy for SCLC.

Pembrolizumab showed similar activity in SCLC. KEYNOTE-028 was a small, nonrandomized, phase 1b study that enrolled patients with previously treated, PD-L1–positive SCLC.[142] KEYNOTE-158 was a larger, single-arm, phase 2 trial that included patients with previously treated SCLC.[143] A pooled analysis of these trials included 83 patients who received pembrolizumab as third-line treatment.[144] In this cohort, the ORR was 19.3%. Although median PFS was limited to 2.0 months and median OS was only 7.7 months, the 24-month OS rate was 20.7%. Pembrolizumab subsequently received accelerated FDA approval as third-line therapy.

First-line Chemoimmunotherapy Combining checkpoint inhibitors with standard platinum plus etoposide chemotherapy in the first-line treatment setting has had an even larger impact on SCLC. IMpower 133 was a global, double-blind, placebo-controlled, phase 3 study that enrolled patients with previously untreated extensive-stage SCLC.[145] Patients were treated with four cycles of carboplatin plus etoposide and were randomized to receive concurrent atezolizumab followed by atezolizumab maintenance therapy or placebo. The combination of atezolizumab with carboplatin and etoposide improved both median PFS and OS and was the first treatment to improve survival for SCLC in more than three decades. The CASPIAN study was an open-label phase 3 study that randomized patients with extensive-stage SCLC to chemotherapy alone or chemotherapy with concurrent durvalumab followed by durvalumab maintenance therapy.[146] Similar to outcomes seen with atezolizumab in IMpower 133, durvalumab improved median OS from 10.3 to 13.0 months (HR, 0.73). Atezolizumab and durvalumab have since been approved with platinum and etoposide as first-line therapy for extensive stage SCLC by the U.S. FDA.

■ Clinical Assessment of Immunotherapy Response

The standard approach to assess response to cancer therapy uses Response Evaluation Criteria in Solid Tumors (RECIST) to provide a consistent approach to evaluate therapy-driven changes in tumor burden. However, tumor response to immunotherapeutic agents differs from that seen with cytotoxic agents. There can be a delayed radiographic response due to the nature of the immune response, which requires T-cell activation, expansion, tumor infiltration, and cell killing before a measurable response is detected. Patients may exhibit stable disease or progressive disease with subsequent response. A response may be mixed with variable changes in different lesions in the same host. Therefore, measurable activity at a tumor site may take longer for immunotherapies than that seen with standard chemotherapy. Four distinct patterns of response have been described: immediate response, stable disease, response after tumor burden increase, and response in the presence of new lesions. Due to the addition of novel responses, immune-related response criteria (irRC) have been developed to allow tumor assessment as a continuous variable.[147]

■ Biomarkers of Clinical Response to Immune Checkpoint Inhibition

Pharmacologic antibodies targeting PD-1 and PD-L1 have resulted in remarkable clinical responses in a subset of patients with lung cancer. However, many patients with lung cancer fail to respond to anti–PD-1/PD-L1 immunotherapy. Moreover, immune-related adverse effects associated with immune checkpoint blockade can limit its use in patients with lung cancer. Thus, it is critical to identify biomarkers that can predict efficacy to immune checkpoint inhibitors in patients with NSCLC.

PD-L1 Expression

Multiple guidelines recommend the use of immunohistochemistry methods to detect PD-L1 expression as a way to predict efficacy of anti–PD-1/PD-L1 immune checkpoint inhibitors in patients with lung cancer. However, there are multiple challenges in using PD-L1 expression as a biomarker of response. A range of commercial kits have been developed to detect different epitopes of PD-L1 utilizing five distinct antibodies on two different immunohistochemistry platforms. Whereas some kits evaluate tumor cells only, other kits evaluate both tumor cells and tumor-infiltrating immune cells. In clinical studies, each pharmacologic anti–PD-1/PD-L1 immune checkpoint inhibitor used a different antibody to evaluate PD-L1 expression in tumors: pembrolizumab used the 22C3 antibody, atezolizumab used the SP142 antibody, nivolumab used the 28-8 antibody, and durvalumab used the SP263 antibody.[148] Moreover, different cutoff values and scoring systems were used to define PD-L1 positivity. The most commonly used method for analyzing PD-L1 expression in NSCLC is the Tumor Proportion Score (TPS), which is the percentage of viable tumor cells showing partial or complete membrane staining for PD-L1 using the 22C3 antibody. In the KEYNOTE clinical trials, pembrolizumab significantly increased OS of NSCLC patients with TPS $\geq$50%.[131,133] However, there are multiple instances of PD-L1–negative NSCLC patients responding to anti–PD-1/PD-L1 immune checkpoint inhibitors, and vice versa, of nonresponders among NSCLC patients with high PD-L1 expression. In addition, PD-1/PD-L1 expression is dynamic and can change over time with therapy. The temporal and spatial heterogeneity in the expression of PD-L1 within NSCLC tumors limits its efficacy as a predictive biomarker. Ultimately, tumor cell killing is T cell–dependent. Therefore, it is likely that PD-L1 expression needs to be considered in the context of the T-cell response, as it is the T-cell functional response that is critical, not PD-L1 expression alone.

Tumor Mutational Burden

Cancer develops through the gradual accumulation of numerous somatic mutations. Although the incidence of mutations varies across tumor types, lung cancer has a high tumor mutational burden (TMB), which is defined as the number of mutations per megabase (Mb) of DNA determined using DNA sequencing. In some studies, high TMB ($\geq$10 mutations/Mb) has been shown to correlate with efficacy of immunotherapy for NSCLC irrespective of PD-L1 expression.[141,149–154] Tumors with a high TMB presumably benefit from immune checkpoint blockade therapy, because high TMB is correlated with the presence of a high number of neoantigens that could be recognized by CD8+ T cells. In theory, any acquired somatic mutation in tumor cells can be a potential neoantigen and can serve as a target for antitumor CD8+ T cells. However, only a small fraction of mutations results in neoantigens recognized by T cells. Several issues limit the utility of TMB as a biomarker of response to immune checkpoint inhibitor therapy in lung cancer. For example, TMB assessment is not standardized across research and clinical studies. Multiple factors can influence the measurement of TMB, including sample quality and quantity, sequencing platform, genome coverage, and bioinformatics analysis pipelines. Thus, TMB can vary between analyses from the same patient sample and between different samples from the same patient.

It is unlikely that a single biomarker will be able to provide all the information necessary to predict tumor response to therapy and dynamically respond to changes in T-cell activation and tumor targets. Perhaps the goal should be to develop panels of markers that will offer targeted therapies (e.g., molecular testing), monitor the tumor (e.g., TMB), and evaluate T-cell responses (e.g., immune checkpoints or other activation/inhibition markers) to guide cancer therapy.

CLINICAL PERSPECTIVE

Below we consider several key clinical areas, including molecular testing methods, the importance of adequate biopsies, acquired resistance to targeted therapy, and the role of so-called liquid biopsies.

Molecular Testing Methods

The identification of novel genetic changes in patients with NSCLC signals a new era of personalized medicine for patients with lung cancer, where it will be imperative to match the specific molecular profile of a patient's tumor with a specific therapy. An important issue to consider is which method will be used for molecular testing. Direct sequencing of PCR-amplified regions of genes that include the most common mutations is the most common method of identifying oncogenic driver mutations (e.g., *EGFR*, *KRAS*). However, testing for gene rearrangements (e.g., *EML4-ALK*, *ROS1*) is typically performed using fluorescence in situ hybridization (FISH). Finally, PD-L1 expression is based on immunohistochemistry. In addition, diagnostic lung cancer samples are frequently small biopsies. The need for multiple molecular tests, which often require distinct diagnostic platforms, is logistically complicated and difficult given the limited amount of available tumor tissue.

Next-generation sequencing (NGS) offers high-throughput sequencing capacity. Unlike PCR-based sequencing techniques, NGS does not require pre-existing knowledge of where to find a mutation. NGS can also provide information PCR-based strategies cannot, such as alternatively spliced transcripts, allele gene variants, and single-nucleotide polymorphisms. This technique provides an opportunity to analyze the entire genome to identify all medically relevant genes using one assay. NGS is already used for NSCLC diagnosis in many hospitals and clinical laboratories, and may eventually replace conventional techniques of gene analysis. NGS is capable of detecting small mutations across all regions of the analyzed genes and may increase the number of identified EGFR or BRAF mutations. However, mutations of unknown significance also may be identified. Although more complicated, NGS analysis of both genomic DNA and RNA can detect more complex alterations, such as *EML4-ALK* rearrangements, *ROS1* fusions, and *MET* exon 14 skipping mutations.[155–158] Evaluation of gene copy number variations (e.g., *MET* and *HER2* amplifications) can be achieved by comparative analysis of the number of reads. However, clinical analysis of protein expression (e.g., PD-L1) cannot be achieved by NGS and requires immunohistochemistry.

Despite obvious advantages, the use of NGS in many circumstances is impractical. NGS requires expensive, sophisticated equipment and reagents, and robust bioinformatics analysis. Thus, NGS may not be available to all medical centers around the world. Druggable mutations in NSCLC are often mutually exclusive, and simultaneous testing for all targetable mutations may not be indicated.[156] For example, the frequency of *EGFR* mutations in Caucasian females or nonsmokers approaches 30%, and in Asians may exceed 70%. Thus, it may be advisable to start testing these subsets of NSCLC patients with a simple and inexpensive EGFR test, and only evaluate for other molecular targets in EGFR mutation–negative patients. In women and nonsmokers, NGS analysis should be considered for "mutation-negative" NSCLC cases, where standard PCR-based sequencing analysis is negative for actionable mutations (i.e., EGFR, ALK, ROS1, BRAF, MET, KRAS, RET, HER2). However, because the vast majority of NSCLCs diagnosed in women and nonsmokers carry a mutation in an actionable mutation, failure to detect a targetable driver mutation may indicate either a technical laboratory error or the presence of a rare but potentially relevant genetic alteration (e.g., NTRK1/2/3, NRAS, NF1), both of which can be detected by NGS.

Importance of Satisfactory Biopsies for Molecular Testing of Lung Cancer

A satisfactory biopsy that allows for both histologic characterization and mutation analysis is becoming increasingly important, both for the diagnosis of lung cancer and for molecular testing. The analytic sensitivity of an assay dictates the quantity of tumor that must be present in the tested sample. For FISH and immunohistochemical analysis, the Molecular Assays in NSCLC Working Group recommended that a tumor tissue section should contain at least 1 to 2 mm^2 of tumor area to provide enough tumor cells for reliable interpretation.[159] FISH results should include hybridization signal counts from at least 100 to 200 tumor cells. Larger amounts of tissue may be required to ensure that sufficient DNA is obtained for mutational analysis as well as avoiding sampling errors due to tumor heterogeneity and the potential for a varying mutational landscape. However, the minimum number of cells needed for mutational analysis by direct sequencing has not been determined. Some studies have suggested a range of 100 to 400 tumor cells.[160,161] The most recent guidelines from the College of American Pathologists (CAP), the International Association for the Study of Lung Cancer (IASLC), and the Association for Molecular Pathology (AMP) recommend using sensitive analytical assays that can detect mutations with tumor cell proportions as low as 20% of the test sample.[162]

Although surgical resection remains the gold standard, the techniques most commonly used for the diagnosis of lung cancer are fiberoptic bronchoscopy and CT-guided transthoracic needle aspiration. Because the majority of patients with NSCLC have advanced disease and are not candidates for surgery, nonsurgical biopsy procedures are preferable. There are limited data on the molecular testing of samples acquired with conventional diagnostic bronchoscopy. For endobronchial tumors, four bronchoscopy biopsy specimens have been shown to be adequate for optimal diagnostic yield.[163] However, biopsy specimens are generally small, averaging approximately 300 malignant cells in aggregate biopsies. In addition, not every biopsy contains tumor cells. Although four specimens may be sufficient to make a diagnosis of lung cancer, they may not provide enough malignant tissue to perform a more detailed molecular analysis. Thus, some authors have recommended that six specimens be obtained from central, endobronchial lesions.[164] The percentage of malignant cells extracted from bronchoscopic samples obtained by bronchial forceps biopsies and endobronchial ultrasound-guided transbronchial needle aspirations (EBUS-TBNA) was compared with surgical biopsies.[165] The median proportion of malignant cells in surgical samples, bronchoscopic forceps biopsy samples, and EBUS-TBNA cell-block samples was 70%, 30%, and 20%, respectively. The frequency of activating EGFR mutations observed was similar in surgical biopsies and bronchoscopic biopsies.

Transbronchial needle aspiration (TBNA) of intrathoracic lymph nodes under endobronchial ultrasound (EBUS) has an increasingly important role in the diagnosis and staging of lung cancer. Several authors have described the successful use of EBUS-TBNA specimens for molecular analysis for *EGFR*, *EML4-ALK*, and *KRAS* gene mutations.[166–168] The concordance rate of mutation analysis between EBUS-TBNA cytologic aspirates and histologic samples obtained by surgical resection have been compared, and all mutations detected in the histologic material of primary tumors were also identified in the cytologic samples.[169] Three needle aspirates from each lymph node stage have been recommended for optimal diagnostic yield. However, the number of needle aspirates needed to obtain sufficient cellular material for molecular analysis has not been determined.

Labarca et al. reviewed the adequacy of EBUS-TBNA samples for molecular analysis in patients with NSCLC and suggested a minimum of three passes with rapid on-site examination (ROSE) or four passes without ROSE to obtain adequate samples for molecular analysis.[170] Although bronchial washes and bronchial brushes can be useful for the diagnosis of lung cancer, they often will not provide enough tumor cells for molecular testing.

For patients with peripheral lung nodules or masses, transthoracic needle aspiration and biopsy are useful procedures. Core-needle biopsy specimens usually contain enough cellular material for molecular analysis (approximately 500 cells per core biopsy). In comparison, a transthoracic needle aspirate obtained using a 21-gauge needle yields approximately 100 cells.[160] Discordance between transthoracic needle aspiration and surgical pathology in the diagnosis of lung cancer may be as high as 39%.[171]

■ Acquired Resistance to Targeted Therapy

As described above, although most NSCLC patients with *EGFR* mutations, *ALK* rearrangements, or *ROS1* fusions respond clinically and radiologically to targeted therapy, the disease always progresses due to acquired resistance. As drug-sensitive NSCLC cells are rapidly eliminated during targeted therapy, the remaining NSCLC cells become adapted to therapeutic pressure, and the molecular profile of lung tumors may significantly change over the treatment course. Thus, defining resistance to targeted therapy is critical for determining whether treatment should be changed. Jackman et al. proposed four criteria for the clinical definition of acquired resistance to EGFR TKIs: clinical exposure to an EGFR TKI, benefit from an EGFR TKI, evidence of disease progression by the RECIST criteria (an increase of 30% in summed maximum diameter or occurrence of new metastatic lesions), and lack of exposure to other drugs.[172] In patients who develop a growing lesion or new metastatic lesion on targeted therapy, we recommend that biopsies be obtained to confirm the presence of disease, and molecular testing should be repeated on these biopsy specimens to identify mechanisms of resistance, such as T790M mutations in the *EGFR* gene, and to direct further therapy. The detection of T790M mutation in TKI-resistant tumors is mandatory prior to initiating osimertinib treatment in TKI-pretreated *EGFR*-mutant NSCLC patients. In some circumstances, NSCLCs acquire TKI resistance by activating other signaling molecules (e.g., EGFR, HER2, ALK, ROS1, MET), a phenomenon that has been termed “kinase switching.” Thus, changing therapy to the appropriate TKI may downregulate the newly activated receptor and lead to clinical responses. As we learn more about the mechanisms of resistance to targeted therapy, we will be able to provide alternative therapies to patients who have disease progression.

However, there is little understanding regarding whether similar principles apply to immunotherapy. Administration of immune checkpoint inhibitors after chemotherapy typically relies on PD-L1 status determined at the time of lung cancer diagnosis (i.e., before the start of systemic treatment). It is important to recognize that second-line trials of immune checkpoint inhibitors did not account for changes in PD-L1 expression induced by chemotherapy.

■ Liquid Biopsies

Many NSCLC patients progress on therapy, developing multiple metastases and tumor foci that may demonstrate heterogeneity with regard to actionable mutations and acquired drug resistance. Obviously, repeated biopsies are not feasible. So-called liquid biopsies may therefore provide valuable insights into tumor evolution during a patient’s treatment course. Liquid biopsies represent the sampling of fluids, usually plasma, for the diagnosis or monitoring of cancer. This noninvasive approach is faster, less morbid, and, in contrast to invasive biopsies, can be performed repeatedly to follow disease. The specimen can be analyzed for soluble, cell-free DNA, some of which will come from the tumor, and circulating tumor cells. However, liquid biopsies have significant limitations, especially since high disease burden is often required for measurable levels of cell-free tumor DNA or circulating tumor cells. Hotspot mutations (e.g., EGFR T790M) can be detected in cell-free DNA or circulating tumor cells using high-sensitivity techniques such as droplet digital PCR.[173] NGS analysis, which is relatively insensitive, is required for more complex evaluations, including sequencing of *ALK* or *ROS1*, multigene tumor profiling, and TMB analysis. In addition, the inability to detect a mutation does not mean cancer is not present, as the amount of cell-free DNA in the circulation may be below detection limits or the cancer may not have a mutation to be detected. Although analysis of circulating tumor DNA will detect acquired mutations, protein expression (e.g., PD-L1) cannot be measured from plasma samples. There is significant interest in developing assays for circulating tumor cells, but it is unclear whether circulating tumor cells are representative of an entire tumor or constitute only a small fraction of cancer cells. Although liquid biopsy may play an important role in the diagnosis and management of lung cancer in the future, at present it should be used as a complementary test to tissue biopsy.

CONCLUSIONS AND PERSPECTIVES

The past two decades have witnessed dramatic success with personalized cancer therapy, and this paradigm shift has led to tremendous improvements in clinical outcomes in patients with molecularly defined subsets of lung cancer. Notably, the identification of a variety of molecular and genetic alternations in NSCLC has provided the opportunity for targeted, personalized therapy, such as EGFR TKIs for activating *EGFR* mutations in NSCLC, ROS1 inhibitors for NSCLC expressing *ROS1* fusions, and ALK inhibitors for NSCLC harboring *ALK* rearrangements. Recent discoveries have led to the development of KRAS^{G12C} inhibitors, which has led to targeted therapy for *KRAS*-mutant lung cancer. The discovery of novel “druggable” driver mutations can lead to swift development of inhibitors of these targets and improved rational combinations of agents. The development of immune checkpoint inhibitors has revolutionized therapy for both NSCLC and SCLC. Critical for their successful application is the development of biomarkers predictive of response. As we gain further understanding of the host immune response and T-cell activation, new drugs that enhance the host antitumor response will be developed. Despite initial responses to targeted therapy, the development of acquired resistance inevitably leads to treatment failure. A greater understanding of tumor resistance mechanisms will also provide additional therapeutic opportunities, leading to improved responses with targeted therapy.

CHAPTER 108

Epidemiology of Lung Cancer

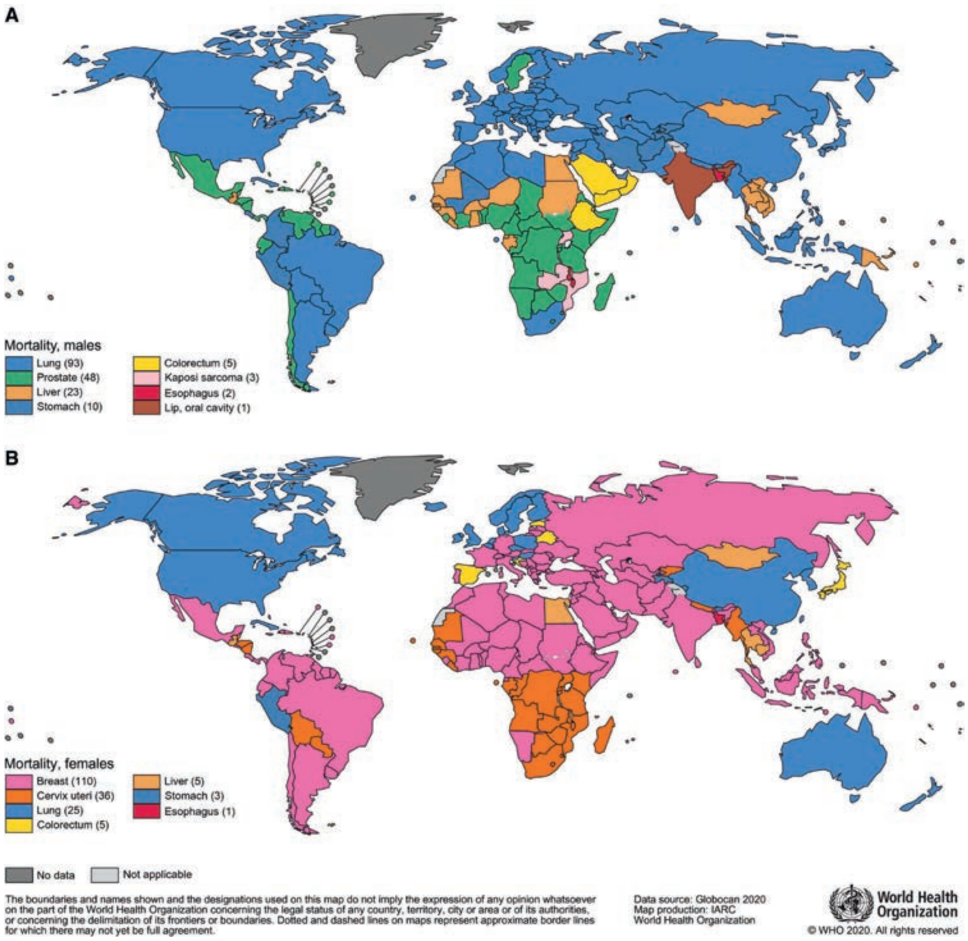
Lynn T. Tanoue
Charles S. Dela Cruz

INTRODUCTION

Lung cancer is the leading cause of cancer death in the world. The International Agency for Research on Cancer (IARC) GLOBOCAN reported a global lung cancer burden of 2.2 million new cases and 1.8 million deaths in 2020 alone.[1] These statistics emphasize the harsh reality that lung cancer is a common and highly fatal disease. Nonetheless, the past decade has witnessed remarkable advances in tobacco control, screening and early detection, and treatment, which are contributing toward progress in curtailing the global lung cancer epidemic.

Globally, lung cancer is the second most commonly diagnosed cancer. It is the leading cause of cancer incidence and mortality in men. In women, it is the third leading cause of cancer incidence after breast and colorectal cancers, and the second leading cause of mortality after breast cancer (Fig. 108-1).[2] Lung cancer is much more common in areas with a high or very high human development index (HDI), such as in Western Europe, the United States, and Japan.[2] The positive association with HDI level mirrors the maturity and extent of the tobacco epidemic in different areas and is stronger in men than in women.[3] Lung cancer incidence and mortality in both women and men in high- and very high-HDI countries historically have been several-fold higher than in countries with low or medium HDI. This will inevitably change given that 80% of current adult smokers live in low- and middle-income countries.[4] The highest lung cancer incidence rates in men are now observed in Eastern and Southern Europe, Eastern and Western Asia, and Micronesia/Polynesia, while in women the highest incidence rates are still observed in North America and Western and Northern Europe.[2] Mortality rates unfortunately closely follow incidence, reflected in an estimated global mortality incidence ratio (MIR) of 0.85.[5] Globally, some improvement has been seen in 5-year lung cancer survival rate, which in most countries is now reported in the range of 10% to 20%.[6] However, compared with the other common solid tumors—breast, colon and prostate cancers—lung cancer outcomes are poor despite the development of a wide array of new therapies, demonstration of lung cancer screening benefit, and advancements in surgical and radiation technologies. Not surprisingly, survival rates are worse in low-income countries without such resources, but poor outcomes still persist even in high-income countries, with 5-year survival in cancer registries in the United Kingdom, Germany, the United States, and Japan reported at 13%, 18%, 21%, and 33%, respectively.[6]

For the purposes of this chapter, the term *lung cancer* includes both non–small-cell lung cancer (NSCLC) and small-cell lung cancer. This distinction and further subclassification (e.g., adenocarcinoma and its subtypes, squamous cell carcinoma, etc.) should be specified in any discussion of lung cancer treatment, which is



The boundaries and names shown and the designations used on this map do not imply the expression of any opinion whatsoever on the part of the World Health Organization concerning the legal status of any country, territory, city or area or of its authorities, or concerning the delimitation of its frontiers or boundaries. Dotted and dashed lines on maps represent approximate border lines for which there may not yet be full agreement.

increasingly more precisely directed by histologic type and biomarkers. From an epidemiologic perspective, many of the risk factors for the different histologic types are shared, in particular risk associated with tobacco smoking, and the distinctions are less pertinent. When relevant, specific cell types are identified in the text.

In the United States, cancer of the lung and bronchus has been the leading cause of cancer death in women since the mid-1980s and in men since the 1950s, resulting in more deaths than breast, colon, and prostate cancers combined (Fig. 108-2).[7] Lung cancer ranks second in cancer incidence in both sexes in the United States, after breast cancer in women and prostate cancer in men. In their annual 2021 report on U.S. lung cancer statistics, Siegel et al. anticipated a total of 235,760 new lung cancer cases and 137,040 deaths from lung cancer, with 119,100 new lung cancer cases in males (12% of all new cancers) and 116,660 new cases in females (13% of all new cancers).[7] The age-adjusted incidence rate of lung cancer was projected at 67.6 per 100,000 men and 51.3 per 100,000 women per year. Lung cancer will continue to be the leading cause of cancer death in both sexes in 2021, with 69,410 deaths anticipated in men and 62,470 deaths anticipated in women, accounting for 22% of all cancer deaths for each sex.

Consider that a decade ago in 2011, there were 221,130 new lung cancer cases and 156,940 deaths.[8] These figures point out that, compared to 10 years ago, more people in the United States are being diagnosed with lung cancer but fewer people are dying. The decline in mortality for lung cancer, particularly in men, accounted for nearly half (46%) of the total decline in cancer mortality in the United States observed from 2014 to 2018.[7] Incidence rates are falling for both men and women, largely reflecting reductions in tobacco consumption since the peak of the tobacco epidemic in the 1970s and 1980s. Nonetheless, the increase in annual lung cancer cases over the past decade is a reminder that the gains made in curtailing lung cancer risk have still been inadequate. Declining lung cancer mortality rates have been observed in men since about 1991 and in women since about 2005 (Fig. 108-2). By inference, more people are surviving because of a remarkable expansion of the array of effective treatments for advanced-stage disease, advancements in surgical and radiation technologies, and a growing ability to personalize treatment for individuals.

The current 5-year survival for lung cancer in the United States is 20.5%.[9] This represents substantial improvement compared to past decades, but the persistently low 5-year survival reflects the fact that more than half of lung cancers are currently identified at advanced stage, when metastasis has occurred and cure is very unlikely. Survival for these patients will be limited even with new therapies. Ultimately, significant improvements in 5-year survival will only be achieved by widespread engagement in screening and early detection.

Lung cancer screening with low-dose chest CT was approved in the United States in 2013, but at present only about 12% of eligible persons undergo screening.[10] The 2021 revision of the lung cancer screening recommendation of the U.S. Preventive Services Task Force (USPSTF) broadened criteria to include a younger population (age 50–80 years) with less intense smoking history (≥20 pack-years of smoking, currently smoking, or having quit within the past 15 years), and is estimated to nearly double the number of persons eligible for screening.[11] Ultimately, successful widespread implementation of lung cancer screening for early detection should begin shifting the preponderance of lung cancer diagnoses from advanced to early-stage disease. This, in combination with continued therapeutic advances, provides hope that substantial improvement in lung cancer mortality will be achieved.

EPIDEMIOLOGY OF LUNG CANCER

At the turn of the 20th century, lung cancer was a rare disease. In a review of autopsy reports from hospitals in the United States and western Europe in 1912, Adler reported that primary lung cancer accounted for <0.5% of all cancers identified.[12] The subsequent epidemic leading to lung cancer being the leading cause of cancer death in the world should be understood in that historic context, as it highlights the important point that lung cancer is a disease caused by modifiable risk factors. If those risk factors were to be controlled, lung cancer could again become uncommon.

■ Tobacco and Lung Cancer

Tobacco smoking is the most important modifiable risk factor for lung cancer. The World Health Organization (WHO) estimates that 1.1 billion persons over the age of 15 currently smoke.[4] Tobacco use is implicated in many cancers other than lung cancer; it has been estimated that up to 20% of all cancer deaths worldwide could be prevented if tobacco smoking were eliminated.[13] More than 90% of lung cancers in men and more than 80% of lung cancers in women develop in smokers. Several studies have reported lung cancer cumulative risk by age 75 among people who are lifelong smokers as high as 16%, compared with a lifetime risk of <1% in nonsmokers.[14,15] In other words, 1 out of 7 lifelong smokers will develop lung cancer. Moreover, smokers will also be vulnerable to excess morbidity and mortality inflicted by other smoking-related diseases, including cardiovascular disease, stroke, and other cancers.

The global lung cancer epidemic is driven largely by tobacco. Understanding the history of the excessive toll cigarettes continue to inflict on human life is a lesson that mass marketing of misinformation compounded by delays in public health interventions can inflict widespread harm. A remarkable expansion of cigarette use starting around the turn of the 20th century was made possible through industrial mechanization of cigarette production and mass advertising crafting socialization of smoking. In the early decades of the 1900s, lung cancer incidence was noted to be disproportionately increasing compared to other cancers.[16,17] Concerns in the scientific community about the deleterious effects of tobacco on longevity in general were heightened by reports that application of smoke condensed from burning of tobacco to the skin of animals produced tumors.[18,19] Subsequent studies demonstrated that tar from the burning of tobacco was carcinogenic, raising concerns that inhalation of tar from cigarettes could be an etiologic factor in lung cancer.[20] In a 1939 review of lung carcinoma, Ochsner and DeBakey stated, "it is our definite conviction that the increase in the incidence of pulmonary carcinoma is due largely to the increase in smoking."[21]

In 1950, two landmark epidemiologic studies established the causal role of tobacco smoking in bronchogenic carcinoma.[22,23] In the United Kingdom, Doll and Hill reported an association between lung cancer and cigarette smoking, including the importance of the intensity and duration of smoking.[23] In the United States, Wynder and Graham examined 605 cases of lung cancer in men and found that 96.5% of lung cancers were in men who were moderate to heavy smokers for many years.[22] They similarly concluded that excessive and prolonged use of tobacco was an important etiologic factor in lung cancer and pointed out that the clinical onset of lung cancer could occur 10 years or more after smoking cessation.

In 1964, the U.S. Surgeon General issued its landmark report on the health consequences of smoking.[24] The key elements of this report were as follows: (1) cigarette smoking was causally related to lung cancer in men; (2) the risk for lung cancer increased with duration of smoking and the number of cigarettes smoked per day; (3) cigarette smoking was associated with a 70% increase in the age-specific death rates of men as well as, to a lesser degree, an increase in the death rates of women; (4) cigarette smoking was believed to be much more important than occupational exposures in the causation of lung cancer in the general population; (5) cigarette smoking was the most important cause of chronic bronchitis in the United States; and (6) male cigarette smokers had a higher death rate from coronary artery disease than male nonsmokers. The report concluded: "Cigarette smoking is a health hazard of sufficient importance in the United States to warrant appropriate remedial action."

The 1964 Surgeon General call to action has been followed by decades of outreach, legal, and regulatory efforts intended to educate the public, curtail marketing of cigarettes to vulnerable populations, and enforce public protections against exposure to tobacco smoke. The cumulative benefit of this multipronged approach is evident in Fig. 108-3, which highlights major public health and regulatory landmarks and demonstrates that U.S. adult per-capita cigarette consumption has steadily decreased since its peak in the mid-1960s.[25] However, despite substantial and meaningful progress, 20.8% (50.6 million) of the entire U.S. adult population are tobacco consumers, 80% of whom are smoking a combustible tobacco product.[26] Fourteen percent of U.S. adults (34.1 million) smoke cigarettes, and 4.5% (10.9 million) use e-cigarettes.

Factors associated with tobacco use are multiple: male sex; younger age (≤65 years); General Educational Development (GED) as the highest level of educational attainment; annual household income <$35,000; lesbian, gay, or bisexual status; Medicaid or other public insurance or uninsured status; and the presence of a disability or anxiety.[26] Tobacco use is also higher among non-Hispanic American Indian/Alaska Native adults (29.3%), non-Hispanic White adults (23.3%), and non-Hispanic Black adults (20.7%) compared with other subpopulations, and more prevalent in those living in the U.S. Midwest and South compared to the U.S. Northeast or West. Geographic variation in lung cancer incidence rates also exposes societal norms that influence tobacco culture in both sexes. Wide variation in lung cancer incidence among states in the United States predominantly reflects the prevalence of smoking, ranging from 109.0 cases per 100,000 men and 77.5 cases per 100,000 women in Kentucky, where 1 out of every 4 residents are current smokers, to 30.2 cases per 100,000 men and 22.5 cases per 100,000 women in Utah, where only 1 out of every 10 residents are current smokers.[7,27] Effective tobacco cessation strategies will need to be designed and implemented with attention to specific factors that influence smoking behaviors in each sector.

■ Cigarettes and Lung Cancer

Lung cancer risk is related to the quantity of cigarette consumption. Factors such as the number of cigarettes smoked per day, the age of onset of smoking and its duration, the tar and nicotine content of cigarettes, the degree of inhalation, and the type of cigarette smoked all contribute to risk.[28,29] The U.S. American Cancer Society Cancer Prevention Study-II (CPS II), the largest cohort study on smoking and lung cancer risk, identified smoking duration as a much stronger predictor of lung cancer mortality than intensity (the amount smoked per day) regardless of age or sex, an observation that is consistent with IARC findings.[30,31] Individual susceptibility is further influenced by environmental and genetic factors.

Cigarette smoke is a complex aerosol composed of more than 5300 gaseous and particulate compounds.[32] *Mainstream smoke* is produced by inhalation of air through the burning cigarette and is

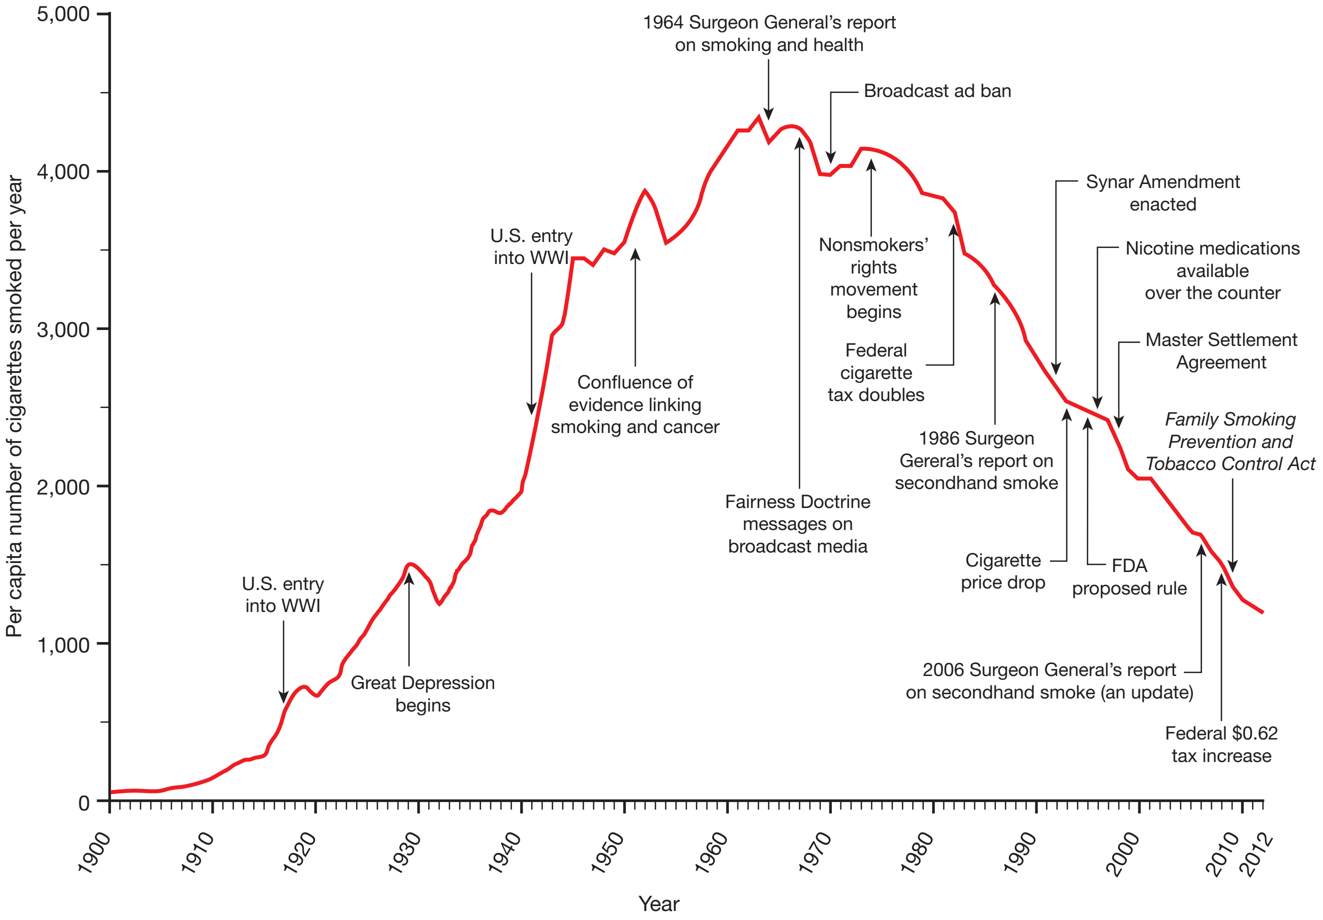

Figure 108-3 Adult per-capita cigarette consumption and major smoking and health events, United States, 1900–2012. *(Reproduced with permission from The Health Consequences of Smoking—50 Years of Progress: A Report of the Surgeon General. National Center for Chronic Disease Prevention and Health Promotion (US) Office on Smoking and Health. Atlanta (GA): Centers for Disease Control and Prevention (US); 2014.)*

the primary source of smoke exposure for the smoker. *Sidestream smoke* is produced from smoldering of the cigarette between puffs and is the major source of environmental tobacco smoke (secondhand smoke). The addictive property of smoking tobacco is attributed to nicotine, the principal alkaloid generated in tobacco smoke.[33] Nicotine and other tobacco alkaloids are not felt to be carcinogenic. The carcinogenic potential of cigarette smoke is related to tar, the solid and liquid residue in cigarette smoke after water and nicotine are removed. The nicotine and tar composition of mainstream smoke varies greatly depending on the tobacco curing (drying) process, chemicals that are added or created during manufacturing of the tobacco product, and the intensity of inhalation by the smoker.

There are more than 1000 different cigarette brands available for purchase in the United States.[34] Cigarette design changes including filtered, flavored, and "low tar" cigarettes do not protect smokers from inhaling carcinogens, and may themselves introduce new toxicants into inhaled smoke.[35] The primary factor determining intensity of cigarette use is the nicotine dependence of the smoker. Smokers of low-yield cigarettes containing less nicotine and tar tend to take more puffs per minute and inhale more deeply to satisfy their nicotine need. This more intensive smoking is also observed with filtered cigarettes. Deeper inhalation exposes higher-order bronchi in the peripheral lung, which lack protective epithelium, to carcinogens in smoke, rather than just the major bronchi. The ability of the smoker to more deeply inhale less irritating smoke is felt to be a contributor to the shift in the predominant lung cancer histologic type from squamous cell carcinoma to adenocarcinoma.[35,36] Moreover, cigarette design changes that decrease the noxious physical effects of inhaling tobacco smoke likely enable more individuals to initiate smoking and nicotine addiction. Public misperception that design changes such as filtration and "low tar" make cigarettes safer has impeded progress in tobacco prevention.

■ Tobacco Smoke Carcinogens

Tobacco smoke contains more than 5300 compounds, of which more than 70 have been identified by the IARC as carcinogens.[31] As early as 1939, Roffo identified the presence of benzopyrene, a polycyclic aromatic hydrocarbon known to be a carcinogenic constituent of coal tar, in cigarette smoke.[37] Carcinogens include polycyclic aromatic hydrocarbons (PAH) such as benzopyrene, N-nitrosamines, aromatic amines, aldehydes, phenols, volatile hydrocarbons such as benzene and 1.3-butadiene, and other organic and inorganic compounds such as ethylene oxide and cadmium.[32]

While many toxic and carcinogenic chemicals are artificially added during the manufacturing process, some occur naturally as tobacco is prepared for use. The agents of particular concern in lung cancer are the tobacco-specific N-nitrosamines (TSNAs) formed by nitrosation of nicotine during the process of curing tobacco and also during the smoking of burning tobacco. TSNAs are present in commercially processed cigarettes, hand-rolled cigarettes and cigars, and bidis and kreteks, which are hand-rolled cigarettes wrapped in nontobacco leaf material and smoked commonly in Southeast Asia. Multiple TSNAs are described, of which 4-(methylnitrosamino)-1(3-pyridyl)-1-butanone (NNK) appears to be the most important in lung carcinogenesis and has also been implicated in cancers of the esophagus, pancreas, and oral cavity. NNK is known to induce DNA adducts and single-strand DNA breakage, and also increases levels of other pulmonary carcinogens, such as 8-osodeoxyguanosine.[38] Failure of the normal DNA repair mechanisms to remove DNA adducts can lead to permanent mutations. NNK can mediate signaling pathway activation that includes modulation of critical oncogenes and tumor suppressor genes promoting uncontrolled cellular proliferation and tumorigenesis.[39] NNK also appears to be associated with DNA mutations resulting in the activation of *KRAS* oncogenes.[40,41] *KRAS* oncogene activation has been detected in 24% of human lung adenocarcinomas [42] and is present in lung adenocarcinoma in ex-smokers, suggesting that such mutations persist even after smoking cessation.[43] This finding may help explain the persistent elevation in lung cancer risk in ex-smokers even years after discontinuing cigarette use. Similarly, benzo(a)pyrene metabolite, a specific chemical constituent of tobacco smoke, can damage various *p53* tumor-suppressor gene loci that are known to be abnormal in approximately 60% of primary lung cancer cases.[44] Related polycyclic aromatic hydrocarbons in tobacco smoke can also target other lung cancer mutational hotspots.[45]

■ Smoking of Cigars, Pipes, and Recreational Drugs

Cigar smoking and pipe smoking are associated with increased risk for lung cancer, although with less risk than with cigarettes. To some extent this may be related to smaller amounts of tobacco being smoked. The tobacco content of a cigar can vary from 1 g to 20 g; on average, smoking five cigars is roughly equivalent to smoking one pack of cigarettes. Cigar smokers have a relative risk of lung cancer of 2.1 to 5.1 compared with nonsmokers; men who smoked five or more cigars a day have the greatest risk.[46] The risk for lung cancer in pipe smokers is similar to that in cigar smokers.[47,48]

The effects of smoking marijuana and cocaine have not been extensively studied. Marijuana smoke contains tar as well as carcinogenic polyaromatic hydrocarbons, similar to tobacco smoke. While an association has not been established between smoking marijuana or cocaine and lung cancer, metaplastic histologic and molecular changes similar to premalignant alterations have been detected in the bronchial epithelium in habitual smokers of these drugs.[49,50]

■ Tobacco Cessation

Tobacco cessation decreases lung cancer risk. Quitting smoking before the age of 40 reduces the risk of death associated with continued smoking by about 90%,[51] and cessation even into the sixth and seventh decades of life is associated with mortality benefit (Fig. 108-4).[14] Even further benefit from smoking cessation is derived from positive effects on vascular disease and nonmalignant pulmonary disease, and decreased risk of other smoking-related cancers.

In 2018, for the first time, the number of men using tobacco globally began to decline despite population growth.[4] Smoking among women worldwide has been declining since 2000.[4] These trends are unfortunately not uniform around the world. In regions where the tobacco epidemic is at an earlier stage, including China, Southeast Asia, and parts of Africa, smoking has either peaked recently or continues to increase (Fig. 108-5).[4] Barring successful interventions to accelerate smoking cessation or reduce smoking initiation, lung cancer rates will likely increase in these areas for at least the next few decades.[4,52,53]

■ Electronic Nicotine Delivery Systems

Electronic nicotine delivery systems include electronic cigarettes (e-cigarettes), e-pens, e-pipes, and e-cigars. These devices produce an aerosol by heating of a liquid containing nicotine and flavorings dissolved in glycerin or propylene glycol. Nicotine is delivered to the user by inhalation ("vaping") of the aerosol. Since around 2011, vaping has rapidly developed into a multibillion-dollar industry. Popularity and social acceptance, particularly among youth, has been fueled by unregulated marketing and chemical flavorings purposefully targeted to a younger audience.[54] In 2020 in the United States, 23.6% of high school students reported current use of any tobacco product, of which e-cigarettes were the most common.[55] Furthermore, 19.6% of students reported current active e-cigarette use compared with 9.4% reporting use of a combustible tobacco product; 8.2% reported using multiple

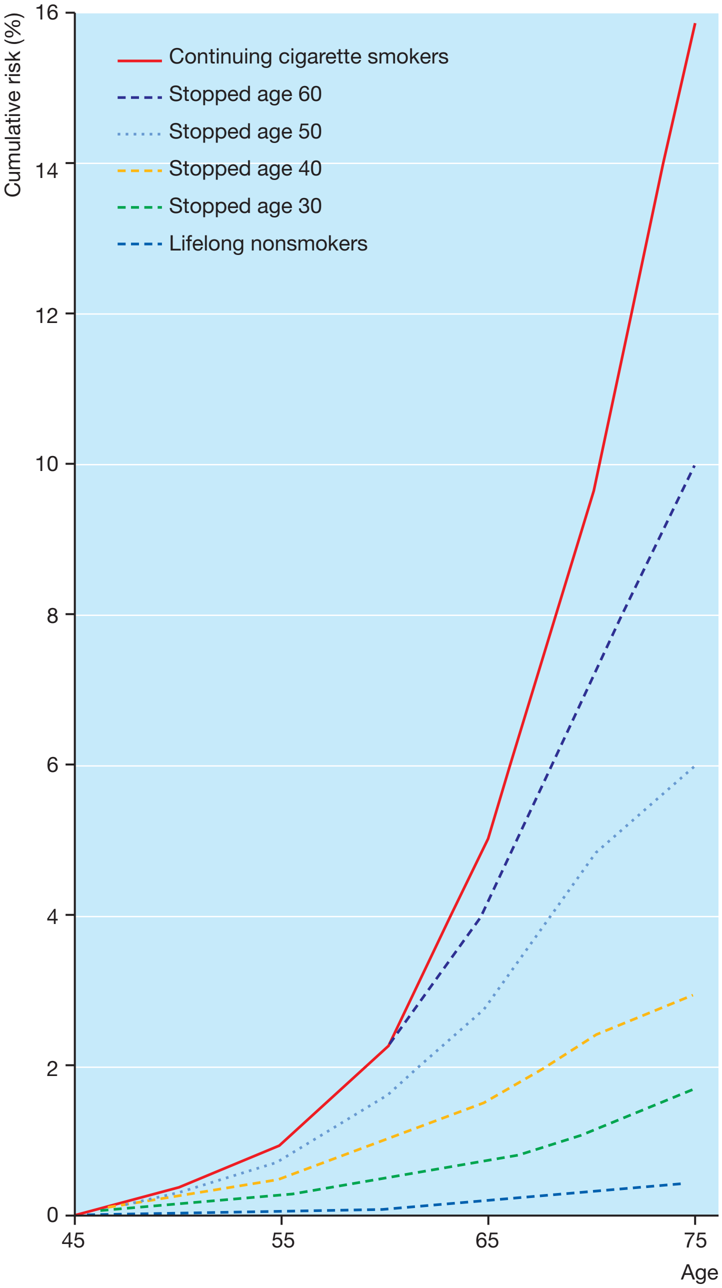

Figure 108-4 Effects of stopping smoking at various ages on the cumulative risk (%) of death from lung cancer up to age 75, at death rates for men in United Kingdom in 1990. *(Reproduced with permission from Peto R, Darby S, Deo H, et al. Smoking, smoking cessation, and lung cancer in the UK since 1950: combination of national statistics with two case-control studies, BMJ. 2000;321(7257):323–329.)*

tobacco products.[55,56] Although it is too early to know long-term consequences, vaping is clearly associated with short-term adverse respiratory outcomes.[57,58] Based on our knowledge of all the long-term health effects of cigarette smoking, it is imperative that regulatory efforts be accelerated given legitimate concerns relating to the perpetuation of future nicotine-addicted generations, the potential for conversion to tobacco cigarette consumption, and the potential for long-term health sequelae including COPD, vascular disease, and lung cancer.[59,60]

■ Never-smokers and Lung Cancer

Never-smokers are defined as persons who have smoked fewer than 100 cigarettes in their lifetime, including lifetime nonsmokers. Lung cancers in never-smokers account for a minority of the global lung cancer burden. However, the absolute number of these cases is substantial, particularly in women, with the incidence of lung cancer in never-smokers being comparable to the rates of cervical cancer in women and myeloma in men.[61,62] Worldwide, an estimated 15% to 20% of lung cancers in men and more than 50% of lung cancers in women occur in never-smokers, with wide geographic variations.[63,64] In the United States, approximately 15% to 20% of cases in women occur in never-smokers compared with 7% to 9% in men; in total, never-smokers account for approximately 10% to 15% of all cases of lung cancer.[65,66] Industrialized countries in Europe report patterns similar to the United States.[64,67–69] In contrast, countries in South Asia report the percentage of women with lung cancer who are never-smokers as high as 83%.[64]

The proportion of lung cancers in never-smokers compared with all lung cancers is increasing. However, there is controversy as to whether the incidence of lung cancer in never-smokers is actually changing, Successful tobacco control efforts, largely in high-income countries, have resulted in a decrease in lung cancer incidence and mortality among smokers, which accounts at least partly for the increase in proportion of never-smokers with lung cancer.

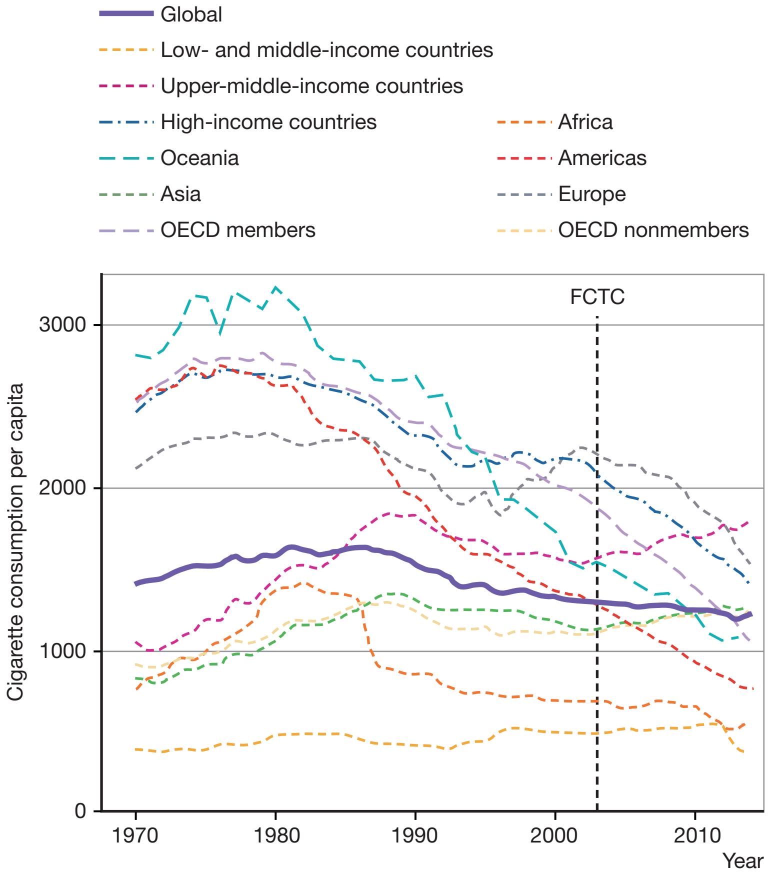

Figure 108-5 Annual population-weighted data on cigarette consumption per capita, by country income level, United Nation region, and Organization for Economic Co-operation and Development (OECD) membership status. Consumption based on number of cigarettes consumed per adult age 15 years or older per year. *(Reproduced with permission from Hoffman SJ, Poirier MJP, Rogers Van Katwyk S, et al. Impact of the WHO Framework Convention on Tobacco Control on global cigarette consumption: quasi-experimental evaluations using interrupted time series analysis and in-sample forecast event modelling, BMJ. 2019;365:l2287.)*

Adenocarcinoma is the predominant histology in never-smokers, exceeding the general trend toward an increase in adenocarcinoma across all cases of lung cancer. Never-smokers are less likely to have highly mutated cancers that are more typical of smoking-related lung cancers, and more likely to have driver mutations. For example, activating mutations in the epidermal growth factor receptor gene (*EGFR*), typically an exon 19 deletion or exon 21 mutation, are identified in 40% to 60% of lung adenocarcinomas in never-smokers, compared to approximately 15% in a general population of lung adenocarcinomas in the United States.[70–74] These and other observations suggest that lung cancer in never-smokers may have distinct biologic behavior and natural history. Microarray gene profiling studies have shown that the profiles of cancer in smokers and never-smokers are quite different.[75,76] In 2010, a genome-wide association study (GWAS) reported genetic variations in never-smoking females in chromosome 13q31.3 that altered the expression of glypican 5 (*GPC5*), a heparin sulfate proteoglycan with many known functions involving cell growth and differentiation and tissue responses.[77] Another GWAS, focusing on lung adenocarcinomas in female Han Chinese never-smokers in Taiwan, identified genetic variation in the *CLPTM1L-TERT* locus of chromosome 5p15.33 to be associated with risk for lung cancer in this population.[78] This 5p15.33 chromosome contains two genes implicated in carcinogenesis, telomerase reverse transcriptase (*TERT*) and cleft lip and palate transmembrane 1-like (*CLPTM1L*).

Risk factors considered to be important for never-smokers include environmental tobacco exposure ("secondhand smoke"), exposures to carcinogens such as radon, outdoor and indoor air pollution, asbestos, arsenic, comorbid lung disease including interstitial lung disease, and genetic factors.[79] A population-based case-control study in Canada found that occupational exposures, history of lung disease, and family history of early-onset cancer were important risk factors for lung cancer among never-smokers.[80] In this study, potential environmental sources of increased risk included exposure to solvents, paints or thinners, welding equipment, and smoke, soot, or exhaust. Other studies have also shown an association between lung cancer in never-smokers and a family history of lung cancer, a finding that suggests a role for heritable variations, for example in pathways involving the human repair gene (*hMSH2*), various cytochrome P450 enzymes, and glutathione-*S*-transferase enzymes.[81–83] Family history may be particularly important in never-smokers. A case-control study following 2400 relatives of 316 never-smokers with lung cancer cases showed a 25% excess risk for cancer in first-degree relatives.[82] Preliminary data from the Taiwan Lung Cancer Screening for Never-Smoker Trial (TALENT) also demonstrate this increased risk.[84] In Taiwan, 53% of lung cancer deaths occur in never-smokers. TALENT included 12,011 never-smoking individuals age 55 to 75 years with a high-risk feature (family history of lung cancer, history of chronic lung disease, cooking without ventilation, and cooking with high intensity of frying). Most (73.8%) study participants were female. Notably, the prevalence of lung cancer over 6 years of follow-up was 2.6%, which was higher than lung cancer detection rates in the U.S. National Lung Screening Trial (NLST) or the Dutch-Belgian Randomized Lung Cancer Screening Trial (NELSON) over similar follow-up duration.[85,86] Moreover, a positive family history of lung cancer was associated with a lung cancer detection rate of 3.2%, with even higher risk observed if the affected family member was a first-degree relation or if there was more than one family member with lung cancer.

The threshold to investigate symptoms in never-smokers is likely to be higher than in smokers because of a lower suspicion of lung cancer, contributing to diagnosis at later stages.[87] Despite this potential for delayed diagnosis, the survival rate for never-smokers is better than for smokers, independent of disease stage, treatment received, or presence of comorbidities.[88–90] A multivariate analysis of survival with lung adenocarcinoma found that never-smoking status was an independent predictor of improved survival, with an overall 25-year survival rate of 23% for never-smokers versus 16% for current smokers.[88]

■ Non-tobacco Factors and Lung Cancer

A wide variety of factors other than tobacco should be considered in the epidemiology of lung cancer, as discussed below.

Age

Lung cancer is predominantly a disease of older persons. In the United States, centralized cancer statistics are reported by the National Cancer Institute Surveillance, Epidemiology, and End Results (SEER) program, which collects data from cancer registries that include approximately 35% of the entire U.S. population. In 2020, SEER data showed that lung cancer was most frequently diagnosed among people age 65 to 74, with a median age at diagnosis of 71years.[9] Of all lung cancer cases, 70.4% occur in persons over the age of 65, with approximately half of those in persons over the age of 75. Only 7.7% of cases occur in in those less than 45 years of age.[9]

Although most cases of lung cancer occur in older persons, smoking prevalence is actually lower in the population older than 65 years than in younger cohorts. Only about 10% of current smokers are older than 65.[26,91] This difference between relatively lower current smoking prevalence and higher cancer rate in the older population in part reflects the latency between smoking exposure and clinical presentation of lung cancer. Approximately 70% of Americans responding to the 2019 National Health Interview Survey self-identified as former smokers of at least 100 cigarettes in their lifetime.[26] Demographic shifts toward older populations in countries such as the United States, Japan, and the United Kingdom and the high prevalence of prior tobacco exposure embedded in these populations imply that the relative magnitude of lung cancer burden in the elderly will continue to increase over the coming decades.[92,93]

Cancer rates in younger as opposed to older populations are felt to be indicators of cancer control efforts.[94,95] The subset of patients with NSCLC under the age of 40 constitutes less than 1% of the entire lung cancer population, but merits separate consideration as they appear to have clinical characteristics distinct from older patients. This group has a higher proportion of women, adenocarcinoma histology, and representation of Asian/Pacific Islanders, and is more likely to present with distant metastases.[94] As with the entire lung cancer population, incidence in young patients is declining. As a group, they have better all-cause and cancer-specific survival than lung cancer patients over the age of 40, although this is not uniform across the United States. Lung cancer mortality in the younger population appears to correlate significantly and inversely with individual state tobacco control efforts, highlighting the importance of regulatory efforts in curtailing tobacco use.[95]

Gender

Globally, the incidence of breast cancer is triple that of lung cancer, but nearly as many women die from lung cancer as from breast cancer.[96] Examination of the epidemiology of lung cancer in women identifies several major areas of interest and concern.

First, in industrialized regions with high HDI such as the United States and much of western Europe, lung cancer in women is largely attributable to cigarette smoking. In the United States, the cigarette smoking rate for women increased during the period from 1930 to 1960. Similar to what had previously been seen in men, a period of latency was followed by an increase in lung cancer in women starting around 1960.[97,98] By the mid-1980s and to the present day, lung cancer surpassed breast cancer as the leading cause of cancer death in women in the United States. At present, nearly twice as many American women die annually of lung cancer than succumb to breast cancer.[8] Since 2005, both lung cancer incidence and mortality in women have been decreasing but at a lesser rate than in men, with the result that the historic male-predominant gender gap is narrowing. In some countries such as the United States, Denmark, and the Netherlands, successively younger birth cohorts show higher female-to-male incidence ratios.[66,99] Anticipated continuation of current trends has resulted in a projection that lung cancer mortality in women will exceed that in men in the United States by 2045.[100]

Second, there remains controversy as to whether women are more susceptible than men to the carcinogenic effects of tobacco smoke. Several older prospective studies did not demonstrate sex-related differences in lung cancer risk related to cigarettes after adjustment for factors including age at onset of smoking, time since quitting, number of cigarettes smoked per day, or pack-years smoked.[101,102] However, more recent studies support the observations that women tend to be diagnosed with lung cancer at a younger age, with less average cigarette use, and with less consumption of non-cigarette tobacco products such as cigars or chewing tobacco.[66,103–105]

Third, women with lung cancer are more likely than men to be never-smokers. As already stated, in the United States, approximately 15% to 20% of lung cancers in women occur in never-smokers, compared with 7% to 9% in men.[65,66] Globally, 53% of lung cancers in women occur in never-smokers, compared with 15% in men. In South Asia, the proportion of female never-smokers with lung cancer has been reported in excess of 80%.[64,67,69] Female never-smokers with lung cancer have a higher likelihood of actionable *EGFR* mutations than men.[72,106,107] Women in low-HDI countries have a higher likelihood of exposures to carcinogens resulting from combustion of biomass fuels for cooking, particularly in poorly ventilated structures.[64]

Lastly, women with lung cancer have improved lung cancer survival compared with men. Multiple large population studies in different countries have demonstrated better outcomes in women than men after adjustment for age, stage of disease, histologic type, and treatment.[108–110] The reasons for this female sex-related survival benefit are not clear. Hormonal factors, in particular the estrogen signaling pathway, have generally been studied as potential contributors to an increased susceptibility of women to carcinogens.[111,112] Estrogen receptors have been demonstrated in lung cancer cell lines and lung cancer tissues, as has aromatase, the rate-limiting enzyme in estrogen synthesis.[113,114] Women over the age of 60 with lung cancer appear to have better survival than younger women, resulting in speculation that the postmenopausal state may be protective.[115] One case-control study showed that estrogen replacement therapy was significantly associated with an increased risk for adenocarcinoma (odds ratio, 1.7), whereas early menopause (age 40 years or younger) was associated with a decreased risk for (odds ratio, 0.3).[116] Sex may

TABLE 108-1 Incidence and Mortality Rates per 100,000 Population for Cancer of the Lung and Bronchus by Race and Ethnicity, United States 2013–2018 and 2008–2012

	Non-Hispanic White	Non-Hispanic Black	Asian/Pacific Islander	American Indian/Alaska Native	Hispanic
Incidence rates, 2013–2017

also be a surrogate for other factors more common in women than men that influence lung cancer prognosis, including never-smoking status, positive *EGFR* mutational status, and lower likelihood of comorbidities.

Race and Ethnicity

Race is a complex variable. Socioeconomic inequalities in wealth are tied to race and ethnicity. It is increasingly appreciated that variations in cancer incidence and outcomes also result from deeply embedded societal structures that maintain racial inequalities and discriminatory practice differences, resulting in excess risk exposures, lower access to health care, and barriers to prevention, early detection, and treatment. Dissecting out possible biologic differences in cancer susceptibility and outcomes between racial and ethnic groups requires that socioeconomic factors be evaluated (see following section).

Table 108-1 outlines lung cancer incidence and mortality rates in the United States from 2013 to 2018 [7] and 2008 to 2012.[117] From 2013 to 2018, lung cancer incidence and mortality rates in men ranged from 37.1 cases and 23.0 deaths per 100,000 persons in Hispanics to 79.8 cases and 57.0 deaths per 100,000 persons in Non-Hispanic Blacks. In women, lung cancer incidence and mortality rates ranged from 24.3 cases and 12.3 deaths per 100,000 persons in Hispanics to 56.4 cases and 35.6 deaths per 100,000 persons in Non-Hispanic Whites. While incidence and mortality both remained higher than observed for most other cancers, it is notable that incidence and mortality decreased during the more recent time period in every racial/ethnic group in both men and women. In men, incidence is highest in non-Hispanic black and lowest in Hispanic males. Mortality is highest in non-Hispanic black and lowest in Hispanic males. In women, incidence is highest in non-Hispanic white and lowest in Asian/Pacific Islander females. Mortality is highest in non-Hispanic white and lowest in Hispanic females. These differences between racial/ethnic groups as well as sex largely reflect historic smoking patterns. Historically, men smoked more than women, and black men smoked more than men of other racial/ethnic groups. These patterns of smoking are changing. Steeper declines in lung cancer incidence and mortality rates have been seen in men compared with women; although fewer women than men smoke, they are slower to quit and an increase in smoking prevalence has been observed in some birth cohorts.[66,118] The narrowing of the disparity gap between lung cancer incidence in black and white men over the past 10 years likely reflects a substantial decrease in smoking prevalence among African-American youth since the 1970s.[119]

Smoking patterns cannot explain all the gaps in incidence and mortality observed between racial and ethnic groups, and important questions persist as to whether certain groups, and specifically African Americans, are more susceptible to lung cancer related to tobacco or other carcinogens. The prospective Multiethnic Cohort Study evaluated more than 215,000 individuals of 5 ethnic groups (African American, Native Hawaiian, Latino, Japanese American, and White) in California and Hawaii and demonstrated significant differences in the association between cigarette smoking and the risk of lung cancer between groups.[120,121] In its original report in 2006, differences were most evident in participants who smoked 11 to 20 cigarettes/day (Table 108-2). For this level of smoking after adjusting for sex, duration of smoking, and time since quitting, and with African-American participants as the reference group, the relative risk (RR) of lung cancer was similar in Native Hawaiians (RR, 0.90; 95% confidence interval [CI], 0.74–1.12) but lower in all other racial/ethnic groups: Latino (RR, 0.36; CI, 0.29–0.44; p <0.001); Japanese American (RR, 0.39; 95% CI, 0.32–0.47; p <0.001); and Whites (RR, 0.57; 95% CI, 0.49–0.63; p <0.001). An update of this study in 2019, at which time the number of lung cancers had increased from 1979 to 4993, demonstrated that these racial/ethnic differences persisted, with higher risk demonstrated in the African American and Native Hawaiian populations and more pronounced risk differences observed in moderate compared to heavy smokers.[121] Multiple other studies have demonstrated similar findings of disparities in lung cancer risk between racial/ethnic groups that cannot be fully explained by smoking patterns.

While most lung cancers are highly mutated from accumulation of somatic genetic changes resulting from cigarette smoke and other carcinogenic exposures, some differences observed between racial/ethnic groups in lung cancer incidence and mortality are likely related to diversity in germline (inherited) genetic variation.[122] This may be more evident in populations with less tobacco exposure. The ability to achieve genomic profiling for individual tumors has made more precise, personalized treatment with improved outcomes a reality for many patients. This unfortunately highlights yet another disparity, as lung tumor mutations have been much more extensively studied in White and Asian than in Black or Hispanic populations.

Racial/ethnic differences have been identified in the frequency of mutation of several genes that can “drive” carcinogenesis. Mutations in the *EGFR* gene are the most commonly identified driver mutations in adenocarcinomas and demonstrate substantial racial/ethnic variation. Actionable *EGFR* mutations are identified in approximately 35% of NSCLC patients in East Asia compared with 10% of patients in western countries.[73,123] Limited and conflicting data are available regarding the frequency of *EGFR* mutations in Black populations.[124–126] A study of 1150 NSCLC biopsies from patients in Argentina, Colombia, Mexico, and Peru showed a wide variation of *EGFR* mutations among the 4 countries, ranging from 19.3% in Argentina to 67% in Peru.[127] The Hispanic/Latinx population in countries of Latin America is likely genetically more diverse than the Hispanic population in the United States, which may account at least in part for such broad variation.[128] Anaplastic lymphoma kinase (*ALK*) oncogenic rearrangements are less commonly seen

TABLE 108-2 Relative Risks of Smoking-related Lung Cancer Among Current and Former Smokers of Five Racial/Ethnic Groups, According to the Level of Smoking[a]

Smoking Level	African American	Native Hawaiian	Latino	Japanese American	White	Global P Value
≤10 Cigarettes/day						
Relative risk (95% CI)[b]	1.00	0.88 (0.60–1.29)	0.21 (0.14–0.31)	0.25 (0.18–0.36)	0.45 (0.34–0.60)

than *EGFR* activating mutations. The most common of these, the *EML4-ALK* fusion gene rearrangement between echinoderm microtubule-associated protein-like 4 (*EML4*) and *ALK*, was originally described in a Japanese population and is observed more frequently in Asian and Latin American compared to White populations.[128,129] *KRAS* mutations, which are the most common driver mutations in lung adenocarcinoma, show a different racial/ethnic pattern than EGFR, with higher frequency in Whites than Asian or Latin American populations.[122,128] Some studies suggest that *KRAS* mutations are of similar frequency in Blacks as in Whites, but without consistent findings.[124–126]

Socioeconomic Status

Sources of wide disparities in lung cancer morbidity and mortality are multifactorial and broad ranging in scope. Factors limiting access to high-quality cancer care include lower socioeconomic or educational status, geographic barriers to tertiary care sites, neighborhood or residential segregation discrimination, lack of access to primary care, and community or cultural trust in the medical system.[130] These same factors will also negatively impact the course and outcomes of other comorbid illnesses that are common among patients with lung cancer, including cardiovascular disease and other smoking-related illnesses, leading to a further compounding of the disparities observed in overall survival.

Lung cancer rates and outcomes are inextricably linked to socioeconomic status, which is a strong determinant of smoking status. Studies in multiple countries have demonstrated that lower income, lower levels of education, and uninsured or public insurance status are associated with higher levels of smoking, higher rates of lung cancer, and worse lung cancer outcomes.[131–134] In 2019, 14% of U.S. adults age 18 or older were current cigarette smokers.[26] The smoking rate among adults with annual household income <$35,000 was 21.4%, compared with 7.1% among adults with household income >$100,000. With regard to education, 35.3% of adults whose highest level of educational attainment was a GED certificate smoked, compared with 6.9% of adults with a college degree. Adults who were uninsured or had Medicaid insurance had smoking rates of 22.5% and 24.9%, respectively, compared with adults with private or Medicare insurance, whose rates were 10.7% and 8.6%, respectively. Other groups with social, economic, and environmental stressors also have higher smoking rates, including American Indian/Alaska Natives, lesbian/gay/bisexual/transgender orientation, divorced/separate/widowed marital status, and persons with disabilities. Further, jobs generating lower income are more likely to be associated with potentially harmful occupational exposures.

Lung cancer rates are higher in Blacks and survival is worse, despite the fact that smoking rates among adults are currently lower in non-Hispanic Blacks (14.9%) than non-Hispanic Whites (15.5%).[26] Race and socioeconomic status are linked to each other and to deeply embedded structural racism that maintains the separation between races and resources and result in unequal access to both preventive and acute health care, disparities in treatment, and differences in outcomes. Several studies have shown that Black patients with early-stage lung cancer are less likely to receive surgical resection than White patients, which undoubtedly contributes to their observed lower survival.[135,136] Cultural factors may create barriers related to beliefs about harms of treatment interventions, but these too may reflect societal structures that foster distrust of the medical system.[137,138] Lower socioeconomic status has also been associated with less timely care and more advanced cancer stage at diagnosis, further contributing to worse prognosis.[136,139–141]

Genetic Factors

Heritable genetic factors influence host susceptibility to carcinogenesis with or without exposure to cigarette smoke, the type of lung cancer that may develop, and individual responsiveness to biologic therapies. A number of studies have shown an association of lung cancer risk with a positive family history of lung cancer, in both smokers and nonsmokers.[142–144] Both genetic as well as shared environmental factors may contribute to this observation. A multicenter case-control study in eastern and central Europe and the United Kingdom including 2861 cases and 3118 controls evaluated the effect of a history of cancer in a first-degree relative (parents, full siblings, children), and demonstrated an increase in lung cancer risk with odds ratio (OR) of 1.63 (95% CI, 1.31–2.01).[145] The same group performed a meta-analysis of 41 studies evaluating the association between a positive family history and lung cancer risk, which demonstrated a significant increase in risk with OR of 1.72 (95% CI, 1.56–1.88).[145] This risk was higher if two or more relatives had lung cancer (OR, 3.60; 95% CI, 1.56–8.31). If the lung cancer case was under the age of 60, the OR for a positive family history was 2.25 (95% CI, 1.61–3.16).

The influence of family history on risk is reflected in its inclusion as an independent factor in several lung cancer risk predictive models. For example, an earlier model developed by Spitz et al. incorporated family history with other significant risk variables including smoking history, exposure to environmental tobacco smoke, and occupational exposures to dusts and to asbestos.[144,146] Similarly, risk models developed from the Liverpool Lung Project (LLP) and the Prostate, Lung, Colorectal and Ovarian (PLCO) Screening Trial include family history as an independent predictive factor. The LLP risk model also identified a significantly increased risk specifically for persons with a family history of early-onset lung cancer (<60 years of age).[147]

While risk related to a positive family history of lung cancer is dwarfed by the magnitude of risk associated with smoking, individual susceptibility to carcinogenic agents can likely be influenced by polymorphisms in genes important in pathways influencing DNA damage response and repair or cell cycle events, as well as chronic inflammation related to smoking or underlying lung disease.[148–151] Genes encoding enzymes involved in repair mechanisms may be influential not only in primary carcinogenesis, but also in response to purposeful DNA damage such as is intended with cytotoxic chemotherapy. For example, the excision repair cross-complementing group 1 (ERCC1) is essential for DNA nucleotide excision repair and is one of multiple genes being studied because of their association with lung cancer susceptibility. Polymorphisms in such DNA repair enzymes may influence lung cancer risk and may also be important in response or resistance to treatment with chemotherapies such as platinum-based drugs, whose therapeutic effect depends on the induction of DNA adducts.[152,153]

Tobacco smoke carcinogens such as the PAHs and N-nitrosamines are predominantly procarcinogens that must undergo metabolic activation to become carcinogenic. Metabolic detoxification also can occur, with the balance between activation and detoxification likely influencing individual lung cancer risk.[32] Mutations and polymorphisms in genes influencing these competing processes can potentially influence an individual's tobacco-related lung cancer risk. Mutations and polymorphisms in genes encoding enzymes involved in the activation and conjugation of tobacco smoke compounds such as PAHs, TSNAs, and aromatic amines have been widely studied. Some of the frequently studied enzymes in this system include CYP1A1, the glutathione *S*-transferases (GST), microsomal epoxide hydrolase 1 (mEH/EPHX1), myeloperoxidase (MPO), N-acetyltransferase 2, and NAD(P)H quinine oxidoreductase 1 (NQO1).[32] A GWAS of tagged single-nucleotide polymorphisms (SNPs) in histologically confirmed NSCLC performed to identify common low-penetrance alleles that influence lung cancer risk identified a susceptibility locus that contains the nicotinic acetylcholine receptor genes.[154] Polymorphisms in genes involved in DNA repair enzymes active in base excision repair (XRCC1, OGG1), nucleotide excision repair (ERCC1, XPD, XPA), and double-strand break repair (XRCC3) and different mismatch repair pathways have been studied as they relate to lung cancer risks.[155,156] Chronic inflammation in response to repetitive tobacco exposure has been theorized to be involved in lung tumorigenesis.[157] Genes encoding for the interleukins (IL-1, IL-6, IL-8) or the cyclooxygenase enzymes (COX2) involved in inflammation, or the metalloproteases (MMP-1, -2, -3, -12) involved in repair during inflammation, and NFKB1 have been associated with lung cancer risk.[158] Various cell cycle–related genes also have been implicated in lung cancer susceptibility, including the tumor suppressor genes *p53* and *p73*, mouse double minute 2 (*MDM2*), and the apoptosis genes encoding FAS and FASL.[159,160] Acquired or epigenetic changes to DNA chromosome also can lead to increased lung cancer susceptibility. These events include changes such as DNA methylation, histone deacetylation, and phosphorylation, all of which can affect gene expression.[161] Moreover, interactions between genes may be as or more important than mutations or epigenetic changes in single genes, emphasizing the complexity of genetic influences in lung cancer susceptibility and development.

Diet

Diets rich in carotenoids, vegetables and fruit, and antioxidants have been proposed as chemopreventive for lung cancer based on several observational epidemiologic studies.[162–166] Conversely, diets rich in red meat, saturated fat, and nitrites have been associated with increased lung cancer risk.[167–169] Rigorous study of the effect of diet and specific chemopreventive interventions on lung cancer risk and prevention is challenging because of the large numbers of subjects and the long duration of follow-up required for such studies.

Enthusiasm for studies of cancer-preventive interventions in lung cancer was tempered in the early 1990s by unexpected harm demonstrated in both the Alpha-Tocopherol Beta-Carotene Prevention (ATBC) trial and the Carotene and Retinol Efficacy Trial (CARET).[170,171] These were large, phase 3, randomized, double-blind, placebo-controlled studies evaluating vitamin supplementation in groups at higher risk for lung cancer, based on epidemiologic evidence suggesting a benefit of dietary beta-carotene on decreasing lung cancer risk. The ATBC subjects were smokers, randomized to beta carotene and/or alpha-tocopherol (a vitamin E isoform) supplementation versus placebo. The CARET subjects were smokers or had asbestos exposure, randomized to beta-carotene and/or retinol (vitamin A) versus placebo. Both studies were terminated early because of excess incidence of lung cancer and overall mortality observed in the intervention groups. Follow-up studies confirmed the persistence for several years of an increased incidence of lung cancer and overall mortality.[172,173]

Subsequent studies, including the Physicians' Health Study and the Women's Health Study, demonstrated neither harm nor benefit with regard to beta-carotene and lung cancer.[174,175] Of note, in contrast to the ATBC and CARET studies, the subject populations of these studies were not exclusively smokers or at higher lung cancer risk, and beta-carotene supplementation doses were considerably lower. It has been postulated that supraphysiologic concentrations of beta-carotene introduced into a free radical–rich environment produced by cigarette smoke may induce oxidation products of beta-carotene, shifting the beta-carotene antioxidant:pro-oxidant balance in the lungs of smokers toward a pro-oxidant state.[176] This hypothesis is supported by a study in ferrets demonstrating that supraphysiologic doses of beta-carotene in smoke-exposed animals increased oxidative metabolites, decreased expression of retinoic acid receptor-β, facilitated the binding of cigarette smoke–derived carcinogens to DNA, and resulted in the development of squamous metaplasia.[177] These findings support concern that supraphysiologic supplementation of nutrients in a population with adequate nutritional status might not be expected to be of benefit, particularly in diseases such as lung cancer with long latency periods.[176,178]

It follows that a diet balanced in nutrients should lead to better health, whereas an unbalanced diet devoid of certain nutrients would lead to worse health, including increased cancer risk. Diets with low or no intake of fruits or vegetables have been associated with up to threefold risk for lung cancer.[179] Diets rich in fruits and vegetables are associated with decreased cancer incidence, with observed protective effects stronger in current than in former smokers.[180] Consumption of vegetables such as carrots that are rich in beta-carotene and cruciferous vegetables such as broccoli and cabbage that are rich in isothiocyanates appears to have some protective effect against lung cancer.[164,181] Raw fruits and vegetables may have better retention of important nutrients such as carotenoids.[182] A large prospective NIH-AARP Diet and Health Study showed no relation between total intake of fruit and vegetables with lung cancer risk.[183] The study did show that higher consumption of several botanical groups such as rosaceae (apples, peaches, strawberries), convolvulaceae (sweet potatoes and yams), and umbelliferae (carrots) was significantly and inversely associated with lung cancer risk in men and in former smokers.[183] Flavonoid plant metabolites have antioxidant and antiproliferative properties and can be found in foods such as berries, citrus fruits, tea, dark chocolate, and red wine. A prospective study demonstrated that risk for lung cancer was lower in men with the highest total flavonoid intake compared to those with the lowest intake.[184]

Obesity and Exercise

In 2016, the World Health Organization estimated that more than 1.9 billion adults were overweight (BMI $\geq$25 and $<$30) or obese (BMI $\geq$30) worldwide.[185] In 2018, 73.6% of the adult U.S. population were overweight and 42.5% were obese.[186] The IARC recognizes obesity as a risk factor for multiple cancers, including cancers of the esophagus, breast, uterus, and liver.[187] No association between obesity and lung cancer risk has been substantiated. One meta-analysis suggested an inverse association between BMI and lung cancer risk, and that obesity might even have a protective role.[188] However, knowing that smokers tend to have lower mean BMI than age- and sex-matched nonsmokers, any association between BMI and lung cancer would need to consider residual strong confounding effects of smoking itself.[189]

Reports on the association between physical activity and lung cancer risk have been limited. In general, positive lifestyle habits such as healthy diet, not smoking, and cardiorespiratory fitness are associated with decreased cancer risk. Several studies in women have demonstrated an inverse relationship between cardiorespiratory fitness and mortality from cancer, predominantly breast cancer.[190–192] In a prospective study of Finnish men, those in the highest tertile of exercise capacity measured by VO_{2max} had a 37% decrease in cancer mortality compared with those in the lowest tertile over an average follow-up of 16.7 years.[193] Most of the observed risk reduction was due to decreased risk of lung cancer in fit men. Whether cardiorespiratory fitness per se decreases risk or whether it is a biomarker for overall healthy lifestyle is unclear but deserves further study.

Benign Acquired Lung Disease and Lung Cancer

Several benign lung diseases are associated with increased lung cancer risk, most notably chronic obstructive pulmonary disease (COPD), interstitial lung disease, and pulmonary infections, particularly tuberculosis. The largest analysis of possible associations was performed by the International Lung Cancer Consortium and included 24,607 lung cancer cases and 81,829 controls, predominantly from Europe and North America, over the period 1984 to 2011.[194] After adjusting for age, sex, and cumulative tobacco smoking, an increased risk of lung cancer was observed with emphysema (RR, 2.44; 95% CI, 1.64–3.62) and chronic bronchitis (RR, 1.47; 95% CI, 1.29–1.68). Increased risk was also demonstrated with a history of pneumonia (RR, 1.57; 95% CI,1.22–2.01) and tuberculosis (RR, 1.48; 95% CI, 1.17–1.87). No sex-related effect was observed. A significant dose–response relation was seen, with increasing risk associated with increasing number of lung diseases.

Why the presence of COPD or any benign lung disease increases the risk of lung cancer is unknown, but it is believed to be most likely related to chronic inflammation.[195] Virchow observed in 1863 that chemical irritant–induced tissue inflammation was associated with cellular proliferation.[195,196] Inflammation may be precipitated by exposure of the airways and lung parenchyma to a variety of insults, including chemicals such as those in cigarette smoke, particulates, and microbial infections. Acute, appropriate immune responses should result in tissue repair. Chronic inflammation resulting in prolonged, persistent tissue injury may create a local microenvironment characterized by rapid local cell turnover, proliferation, and angiogenesis. Long-term chronic systemic inflammation also has been implicated in increasing the risk of lung cancer, suggesting that circulating inflammatory cells may also act as carcinogenic promoters.[197,198] Several studies have demonstrated that elevated C-reactive protein (CRP), which is released by the liver in response to systemic inflammation or tissue injury, may be a biomarker for increased risk of lung cancer and bronchial dysplasia.[198–200]

COPD is the second most common risk factor for lung cancer after smoking. Cigarette smoking is the primary cause of both lung cancer and COPD. Multiple studies have consistently demonstrated that the presence of COPD, characterized by irreversible obstruction to airflow, is associated with a higher risk of lung cancer.[201–203] While there has been debate as to whether the severity of airflow limitation correlates with the risk of lung cancer, observations from several studies support this hypothesis.[204–207] In particular, a prospective analysis of a subgroup of 18,473 high-risk cigarette smokers in the National Lung Screening Trial demonstrated a linear relationship between increasing severity of airflow limitation and risk of lung cancer.[208] Lung remodeling in general has been linked to both COPD and lung cancer Additionally, epithelial–mesenchymal transition, which is considered a precursor to many epithelial cancers including lung cancer, has been observed in patients with COPD and is associated with worsening airflow limitation.[209,210]

The understanding that chronic airflow limitation may increase the risk of lung cancer through inflammatory mechanisms led to studies examining the possible chemoprotective effect of inhaled corticosteroids (ICS). A large retrospective study of patients with COPD found that the risk for lung cancer was lower in patients who took high-dose inhaled corticosteroids than in patients taking lower doses or none at all.[211] However, subsequent randomized controlled trials and a systematic review failed to confirm this observation.[212]

Interstitial lung disease has emerged as a potential contributor to lung cancer risk. This is a very broad statement, as the interstitial lung diseases are a heterogeneous group of more than a hundred diseases with varying pathogenesis, associations, and prognosis. Repeated lung injury and lung cancer may share biologic mechanisms with carcinogenesis, for example fibroblast proliferation and epithelial–mesenchymal transition can lead to remodeling, genetic mutations, and dysplasia. Of the interstitial diseases, idiopathic pulmonary fibrosis (IPF) appears to have the most consistent association with lung cancer. While a large analysis of mortality data in the United States reported that lung cancer occurred less frequently in patients with pulmonary fibrosis compared to the general population, that conclusion is weakened by the limitations of death certificate data to reliably identify diagnoses such as interstitial lung disease, particularly if it were mild and not recognized as contributing to death.[213] Other series have reported an increased incidence of lung cancer in patients with IPF compared to the general population, predominantly in men and ever-smokers.[214–218] The strongest evidence for an independent association of IPF and lung cancer was presented in a population-based cohort study involving 890 subjects with cryptogenic fibrosing alveolitis (idiopathic pulmonary fibrosis) and 5884 control subjects in the United Kingdom, in which the incidence of lung cancer after adjustment for previous smoking was markedly increased (OR, 8.25; 95% CI, 4.70–11.48).[217]

Infections

Pulmonary infections are clearly associated with inflammation. Chronic pulmonary infection, in particular tuberculosis, may result in prolonged pulmonary as well as systemic inflammation lasting months to years. Treatment itself typically requires a duration of at least 6 months, and lung remodeling with resultant bronchiectasis and fibrosis is well described. A large population-based cohort study performed in Taiwan showed that patients with tuberculosis (N = 4480) were 10.9 times more likely to develop lung cancer compared to patients without tuberculosis (HR, 3.32; 95% CI, 2.70–4.09).[219] This study is limited by potential confounding for tobacco use, which was not reported. Other smaller case-control studies suggest that an association between tuberculosis and lung cancer risk exists with odds ratios in the 2–4 range, but this was not significant in the absence of a history of smoking.[220,221]

Acute bacterial pneumonia, for example caused by organisms such as *Streptococcus pneumoniae*, typically does not result in prolonged episodes of chronic inflammation. While there has been some suggestion of an association between prior pneumonia and subsequent lung cancer risk, in general these associations are fairly weak.[195,220,222] One exception to this may be *Chlamydia pneumoniae,* which is felt to be the cause of approximately 10% of community-acquired pneumonia. Several case-control studies have demonstrated an association of *C. pneumoniae* infection with lung cancer.[223–227] A nested case-control study within the screening arm of the PLCO Trial demonstrated that seropositivity for chlamydia heat shock protein 60 antibodies, a marker for chronic chlamydial infection, was associated with an increase in lung cancer risk (OR, 1.30; 95% CI, 1.02–1.67) independent of smoking or histology, and that risk increased with increasing antibody titers.[226] Notably, this association was not seen with seropositivity with microimmunofluorescence IgG or IgA antibodies, suggesting that the chronicity of *C. pneumoniae* infection and pulmonary inflammation might be important in contributing to lung cancer risk.

Multiple studies have demonstrated an increased risk of lung cancer in patients with HIV. At least some of the excess risk appears to be attributable to high smoking prevalence in the HIV-infected population.[228,229] However, several studies suggest that the increase in risk for lung cancer cannot be explained by smoking alone.[228–230] In a study including nearly 400,000 patients with AIDS in the United States, lung cancer risk compared to the general population was increased in all demographic groups, with the relative risk greatest in the youngest age group (standardized incidence ratio 10.4 for ages 15–29 years, 6.3 for ages 30–39 years, 3.7 for ages 40–49 years).[231] While this study did not include individual-level smoking data, an analysis based on plausible patterns of tobacco use noted a higher lung cancer risk than could be attributed to smoking alone. In a study of 2086 injection drug users including HIV-infected and HIV-uninfected groups where smoking history was known, an increased risk of lung cancer was demonstrated after adjustment for tobacco use (RR, 3.4; 95% CI, 1.6–7.4).[229] Notably, although the prevalence of smoking in the HIV-infected population is very high, there is little evidence of an increase in lung cancer in HIV-infected never-smokers.[195] This raises the possibility that HIV is a cofactor with tobacco in lung carcinogenesis. Additionally, HIV infection may invoke a likelihood of chronic inflammation, given its association with increased risk of bacterial infection and opportunistic infections, as well as a higher prevalence of coinfection with oncogenic viruses such as human herpesvirus 8, human papillomavirus (HPV), and Epstein-Barr virus.[232]

Oncogenic viruses have been proposed as potential contributors to lung carcinogenesis. Analysis of the Cancer Genome Atlas data identified viral sequences of eight viruses in lung cancers compared with paired adjacent normal tissues, including HPV16, HPV18, HPV30, HPV33, human herpesvirus 4 (Epstein-Barr virus), human herpesvirus 5 (cytomegalovirus), human herpesvirus 6, and hepatitis B virus.[233] Several of these viruses are known to be associated with other solid tumors, for example HPV16 and HPV18 with cervical cancer and cancers of the head and neck, and human herpesvirus 4 with Burkitt lymphoma and nasopharyngeal carcinoma.[234,235] Distribution of these viruses varies by sex as well as by race/ethnicity. There has not been consistent association of any of these or other viruses with lung cancer, but recognition of their etiologic role in other cancers suggests that further research in this area should be pursued.

Environmental Tobacco Smoke

Environmental tobacco smoke (ETS), also referred to as “secondhand smoke,” consists of mainstream (exhaled) smoke and sidestream (from the burning tip of the cigarette) smoke. Many organizations and governments, including the IARC, the U.S. Department of Health and Human Services, and the U.S. Environmental Protection Agency (EPA), classify ETS as containing multiple lung carcinogens.

A number of studies support the hypothesis that ETS is an important risk for lung cancer, although the magnitude of risk is problematic to measure as quantifying ETS exposure is difficult. In 1986, the U.S. National Research Council commissioned a review of the effects of ETS as a potential causal agent of lung cancer in nonsmokers exposed to household cigarette smoke.[236] Review of all the available evidence yielded an overall increase in lung cancer risk associate with ETS with OR of 1.34. In smokers, this increase in risk may be trivial. In never-smokers, this translates into an approximately 34% increase of risk for lung cancer. It important to note that since the background risk for lung cancer in a never-smoker is very low, such an increase will not substantively change that risk.[236,237] A meta-analysis including 40 case-control and prospective cohort studies evaluating the effect of secondhand smoke on never-smoking subjects showed an increased hazard ratio (HR) of 1.22 for developing lung cancer (95% CI, 1.13–1.33; $p < 0.001$).[238] Another meta-analysis evaluating lung cancer in never-smoking women exposed to a smoking spouse reported a pooled RR of 1.27 (95% CI, 1.17–1.37).[239] A case-control study done in the United States demonstrated an increased risk of lung cancer in never-smokers with secondhand smoke exposure in childhood, with OR of 1.47 (95% CI, 1.04–4.90).[240] These and other studies support the conclusion that ETS is an important risk factor for lung cancer, particularly among never-smokers.

Environmental Pollution

Outdoor air pollution is associated with lung cancer risk. Early studies involving urban-rural comparisons showed that an “urban factor" was associated with a 10% to 40% increase in lung cancer deaths.[241] Outdoor air pollution particulate matter (PM) is designated by the IARC as carcinogenic in human. Analytic methods to detect specific pollutants often use the concentration of suspended fine airborne particulates as a measure of air pollution. PM with aerodynamic diameters of <10 μm (PM_{10}) and 2.5 μm ($PM_{2.5}$) have been reported as associated with risk of lung cancer.[242] Two large U.S. cohort studies estimated a 19% excess risk for lung cancer per 10-μg/m^3 increment in long-term average exposure to fine particulates.[243,244] The Cancer Prevention II study found that fine particulate ($PM_{2.5}$) and sulfur oxide–related pollution were associated with an 8% increased risk for lung cancer mortality for each 10-μg/m^3 elevation in long-term average ambient concentration.[244] A meta-analysis of this and 17 other studies concluded that lung cancer risk increased for every 10-μg/m^3 increase in exposure to $PM_{2.5}$ (meta-analysis RR, 1.09; 95% CI, 1.04–1.14), with risk being more pronounced in former (meta-analysis RR, 1.44; 95% CI, 1.04–1.22]) and never-smokers (meta-analysis RR, 1.18; 95% CI, 1.00–1.39]).[245] Debate persists as to whether chemicals adherent to the particulates or the particulates themselves are the relevant carcinogenic exposure.[246]

It is difficult to determine the carcinogenicity of single constituents of air pollution. Combustion products of fossil fuels such as coal and oil also have potential carcinogenic components. In many parts of the world, solid fuels such as wood are burned as primary sources of domestic energy for cooking and heating. Incomplete combustion of coal in homes has been linked with lung cancer, particularly among women in Asia.[247–249] The IARC has classified indoor emission from household coal combustion as a human carcinogen and emissions from biomass fuel, primarily from wood, as a probable human carcinogen. Diesel exhaust, which is composed of a complex mixture of gases and fine particles, is also an important component of air pollution and an occupational exposure for persons in the trucking industry. Some of the gaseous components of diesel exhaust, including benzene, formaldehyde, and 1,3-butadiene, are suspected of or known to cause cancer in humans. A pooled analysis of 11 studies evaluating diesel exhaust exposure and risk of lung cancer demonstrated an increased risk with OR of 1.31 (95% CI, 1.19–1.43).[250]

TABLE 108-3 Selected Occupational Carcinogens and Associated Exposures

Carcinogen	Occupational Exposure
Arsenic	Copper, lead, or zinc ore smelting Manufacture of insecticides Mining
Asbestos	Asbestos mining Asbestos textile production Brake lining work Insulation work Shipyard work
Beryllium	Ceramic manufacture Electronic and aerospace equipment Mining
Chloromethyl ethers	Chemical manufacturing
Chromium	Chromate production Chromium electroplating Leather tanning Pigment production
Diesel	Trucking industry
Nickel	Nickel mining, refining, electroplating Production of stainless and heat-resistant steel Aluminum production Coke production Ferrochromium alloy production
Particulate matter (PM_{25})	Air pollution
Radon	Mining

Occupational Carcinogens

Lung cancer is the most common cancer associated with occupational exposures, which should be modifiable and preventable. The IARC has implicated a number of occupational carcinogens in lung cancer.[251] A selection of these agents and their associated occupations are shown in Table 108-3. An estimated 10% of lung cancer deaths in men and 5% in women worldwide could be attributable to exposure to eight occupational lung carcinogens, specifically asbestos, arsenic, beryllium, cadmium, chromium, nickel, silica, and diesel fumes.[252–255] The U.S. National Institute for Occupational Safety and Health (NIOSH) estimated that approximately 9000 to 10,000 men and 900 to 1900 women per year in the United States develop lung cancer from exposure to occupational carcinogens.[256] Given that lung carcinogenesis for smoking-related lung cancer is a multistage process, these assessments may underestimate the carcinogenic contribution of occupational and environmental exposures occurring over time.[257]

Asbestos is the most common occupational cause of lung cancer. Asbestos, a naturally occurring fibrous mineral, can be classified as serpentine (chrysotile) or amphibole (amosite, crocidolite, tremolite). Asbestos has been used in construction and as insulating material for its fire-retarding qualities and strength since the 1800s, but its role as a lung carcinogen was not established until the 1940s. While asbestos mining in the United States has ceased, asbestos per se is not banned on a federal level, and while asbestos is regulated by the EPA and some states have enacted legislative controls, asbestos can still be imported and used in the United States in small amounts. Fortunately, asbestos use has precipitously declined in the United States since the 1970s.[258,259]

Asbestos exposure is a risk factor for lung cancer as well as mesothelioma. Lung cancer related to asbestos is predominantly related to occupational exposure, with risk from nonoccupational asbestos exposure in the general environment being extremely low.[260] All commercial asbestos fiber types can be associated with lung cancer. Risk is dose-dependent without a clear minimum threshold of exposure.

It is important to recognize that cigarette smoke use contributes significantly to lung cancer risk in asbestos-exposed individuals. Debate continues as to whether exposure to the combination of smoking and asbestos results in a multiplicative or additive increase in risk, although the burden of studies suggest that the effect is more than additive.[261–266] There has also been notable controversy as to whether interstitial fibrosis related to asbestos exposure (asbestosis) is a prerequisite for lung cancer risk. In early animal studies, asbestos-exposed animals developed lung cancer only when they also developed pulmonary fibrosis,[267,268] and human studies reported that the presence of asbestosis was associated with increased likelihood of lung cancer compared to patients with asbestos exposure without associated fibrosis.[258,269] However, there is understandable dispute as to whether one, any, or all patterns of interstitial lung disease (idiopathic pulmonary fibrosis, nonspecific interstitial pneumonia, unclassified interstitial changes) can be called asbestosis in the absence of pathologic evidence of asbestos bodies. Further complexity relates to limitations imposed by the lack of pathologic evidence of asbestos bodies without an invasive procedure, or occult interstitial disease that may be subradiographic even with high-resolution chest CT scanning.[263,270]

Radon and its decay products are carcinogens associated with mining, one of the world's oldest occupations. Initially known as a wasting pulmonary disease of miners and metal smelters, radon-induced lung cancer was first attributed to exposures to dust or metals, or to infections such as tuberculosis, but was later linked to radioactive materials.[271] Uranium mining has ceased in the United States. However, radon exposure continues to be an occupational concern in non-uranium mining and underground work as well as in uranium and non-uranium mines around the world.[272] In the United States, occupational exposure to radon is strictly regulated. It has been estimated that a 40-year radon exposure at the maximum allowed level by occupational standards would increase a person's lifetime risk for lung cancer twofold.[273]

Radon is a natural decay product of radium 226, itself a decay product of uranium 238. Ultimately, radon decay produces lead 210, which has a half-life of 22 years. Both uranium and radium are ubiquitous in soil and rock, in highly variable concentrations. At usual temperatures, radon is released as an inert radioactive gas. Radon has a half-life of 3.82 days and decays into radioisotopes known as radon decay products (or radon daughters) that have half-lives measured in seconds to minutes. These products include polonium 218 and polonium 214, which emit alpha particles. It is the alpha radiation that is highly damaging to tissues including the respiratory epithelium. Inhalation of these radon decay products and subsequent alpha particle emission in the lung can cause damage to cells and genetic material. Evidence from epidemiologic studies of underground miners shows a linear relationship between radon exposure and lung cancer risk.[274,275] Uranium miners exposed to radon and its decay products have an increased risk for lung cancer, peaking 15 to 24 years after exposure.[276] A pooled analysis of 11 cohort studies including 2700 lung cancer deaths occurring in 65,000 miners concluded that the relative risk for lung cancer was linearly related to cumulative radon progeny exposure, and that 40% of all lung cancer deaths in their cohort might be due to such exposure.[277] In never-smokers, 70% of lung cancer deaths were thought attributable to radon progeny exposure.[277] Other studies support an increased risk of lung cancer in never-smokers with higher levels of uranium exposures.[277,278] The combination of uranium exposure and smoking appears to have a synergistic effect in increasing lung cancer risk in miners.[279–281]

Radon is a ubiquitous domestic indoor air pollutant and is classified by IARC as carcinogenic to humans. The U.S. National Council on Radiation Protection and Measurements has identified radon and its decay products as the largest component of environmental radiation to persons living in the United States.[275] Case-control studies identify domestic radon as increasing the risk of lung cancer.[282,283] A meta-analysis including 8 studies with 4263 lung cancer cases and 6612 controls concluded that higher residential radon levels were associated with an increase in lung cancer risk with RR of 1.14 (95% CI, 1.0–1.3).[272] In the United States, the EPA estimates that approximately 21,000 lung cancer deaths annually are attributable to radon.[284]

The concentration of radon gas in an environment depends on the richness of the source of radium and the degree to which the air around that source is ventilated. The primary factor determining radon gas concentration in homes is the concentration of radium in the soil and rock beneath those structures.[279] Building materials, well water, and natural gas are less common sources, usually contributing only minimally to indoor radon concentrations. Radon mitigation can usually be accomplished by installation of ventilation systems that exhaust radon from the home to the outside environment.

PERSPECTIVE AND CONCLUSIONS

Seven decades have passed since cigarettes were linked causally to lung cancer. What was a rare disease at the turn of the 20th century now causes 1.8 million deaths each year. Each decade has witnessed new understanding about other exposures that contribute to lung cancer risk. The knowledge that lung carcinogenesis is in most cases a cumulative process of genetic and epigenetic changes caused by largely preventable exposures provides a roadmap for mitigation.

Insights into the epidemiology and causal factors of lung cancer provide a sound foundation for disease prevention. The most important preventive strategy is to aggressively curtail cigarette consumption. The WHO Framework Convention on Tobacco Control (FCTC) treaty developed the MPOWER policy package, with the intention that countries would implement individual policies to (1) monitor tobacco use, (2) protect people from tobacco smoke, (3) offer help to quit tobacco use, (4) warn about the dangers of tobacco, (5) enforce bans on tobacco advertising, promotion, and sponsorship, and (6) raise taxes on tobacco products.[285] These policies acknowledge that tobacco control requires interventions at public health, legislative, regulatory, and personal behavioral levels. Whether the FCTC per se has changed the international agenda on tobacco, such policies alone and in combination have led to declining tobacco use in high-HDI countries, and provide a strategy for low- and middle-income countries where tobacco use is still on the rise.[286]

Our knowledge of lung cancer epidemiologic factors also identifies groups at particular risk. Lung cancer is a significant women's health issue; lung cancer incidence rates are declining more slowly in women than in men, with a worrisome narrowing of the gender gap in lung cancer mortality. Groups that live under structural bias related to race and ethnicity or subject to socioeconomic and environmental stressors are more likely to smoke and less likely to have access to preventive or primary care as well as to state of the art precision treatments. Vaping of nicotine is still largely unregulated. Occupational and domestic carcinogens, including air pollution, are prevalent. Populations with these demographics and exposures warrant specific attention, further study, and targeted interventions.

Tobacco control remains a global imperative. Predictive models for lung cancer risk developed over the past 15 years acknowledge the influence of non-tobacco factors, but it is clear that risk is overwhelmingly dominated by tobacco exposure.[146,147,287] High HDI nations are beginning to emerge from the peaks of their individual lung cancer epidemics. Other nations should not be held hostage to tobacco or subjugated to the health and economic consequences of tobacco-related diseases such as lung cancer. Primary prevention curtailing tobacco use must be an international priority.

CHAPTER 109

Lung Cancer Screening

Humberto K. Choi
Peter J. Mazzone

INTRODUCTION

Lung cancer is the leading cause of cancer-related deaths in the United States,[1] in part because most cases are diagnosed at advanced stages when the prognosis is poor.[1] The development of tools to detect early-stage lung cancer has the potential to dramatically impact lung cancer outcomes.

Screening refers to testing an individual at risk for a disease before they have symptoms or signs of the disease in order to detect the disease at an earlier stage, when curative intent treatment is more successful. Over the past few decades, large clinical research studies have evaluated lung cancer screening tests. Screening with chest radiography (CXR) and sputum cytology failed to demonstrate a reduction in lung cancer mortality. Early cohort studies evaluating screening with low-dose computed tomography (LDCT) were more promising, prompting controlled trials that have shown reduced lung cancer–related mortality in a group at high risk for developing lung cancer.[2,3] Low-dose computed tomography is now an accepted lung cancer screening test.[4] More than just a lung scan, screening involves appropriate patient selection, consideration of benefits and potential harms, performance and interpretation of the LDCT, and management of screen-detected findings. Lung cancer screening is a complex task requiring a multidisciplinary, comprehensive program. Additional discussion of this topic is provided in Chapter 28.

LUNG CANCER SCREENING EVIDENCE BASE

Chest radiography and sputum cytology have been evaluated as lung cancer screening tools.[5–7] Despite improved survival of screen-detected lung cancers in cohort trials, controlled trials failed to demonstrate a reduction in lung cancer mortality in the screening arms. Advances in chest imaging shifted the interest toward LDCT as a screening test given its higher sensitivity to detect small tumors.

The Early Lung Cancer Action Project and other cohort studies demonstrated that LDCT could detect more lung nodules and early-stage lung cancers than CXR.[8] These promising results led to the development of controlled trials to investigate whether LDCT could reduce lung cancer mortality (Table 109-1).[2,3,9–15] The National Lung Screening Trial (NLST) and Dutch-Belgian lung cancer screening trial (Nederlands-Leuvens Longkanker Screenings Onderzoek [NELSON]) are the only trials published to date that were powered to detect differences in lung cancer–specific mortality.[2,3]

The NLST was conducted between 2002 and 2009 at 33 medical centers in the United States. It was the first lung cancer screening randomized controlled trial to report a significant reduction in lung cancer mortality.[2] The inclusion criteria were an age of 55 to 74 years, a smoking history of at least 30 pack-years, and either current smokers or former smokers who had quit within the past 15 years. The trial enrolled 53,456 participants who were randomized to LDCT or to CXR screening with a baseline test followed by two annual LDCT or CXR rounds. Participants had 6 to 7 years of follow-up. LDCT scans that revealed any noncalcified nodule measuring at least 4 mm in diameter and CXR images that revealed any noncalcified nodule or mass were classified as positive. Screening with LDCT resulted in a 16% to 20% relative reduction in the rate of death due to lung cancer. The trial also showed a 6.7% reduction in all-cause mortality with LDCT screening. In absolute terms, for every 320 subjects screened with LDCT 1 death due to lung cancer was prevented.

The NELSON trial started in 2000 and enrolled participants age 50 to 74 years who smoked 15 or more cigarettes a day for more than 25 years or 10 or more cigarettes a day for more than 30 years, and smoked within the past 10 years. More than 13,000 male participants were enrolled and randomized to 4 rounds of screening with LDCT (baseline and years 1, 3, and 5.5) or to no screening. Participants were followed for 10 years. The trial used semiautomated software to segment lung nodules and determine the nodule volume. Based on the volume of the nodule, a screening scan could be negative, indeterminate (requiring a 3-month follow-up scan to assess for volume doubling time), or positive. The trial demonstrated a significant lung cancer–specific mortality reduction of 24% with LDCT screening. The primary analysis included only men, as a small number of women were enrolled. Women were included in a subgroup analysis that revealed a reduction in lung cancer mortality of 33% (not statistically significant).

ELIGIBILITY

The positive results from NLST led to enthusiasm to bring LDCT screening into clinical practice. Several professional societies endorsed LDCT screening based on the NLST eligibility criteria (Table 109-1).[16–19] In 2013, the U.S. Preventive Services Task Force (USPSTF) recommended annual LDCT screening for individuals between 55 and 80 years who have at least a 30-pack-year smoking history and who currently smoke or who have quit within the last 15 years.[4] The recommended expansion of the age criteria from 55–74 years to 55–80 years was based on simulation models that estimated long-term harms and benefits of screening.[20] Of the 576 scenarios simulated (different starting and ending ages, pack-years, years since quit, and frequency of screening), annual screening of individuals with at least 30 pack-years of smoking who have smoked within the past 15 years and are between the ages of 55 and 80 years was selected from among the scenarios that demonstrated the most efficient balance of benefit and harms.[20] Separately, the Centers for Medicare and Medicaid Services (CMS) evaluated the evidence for coverage of lung cancer screening in the Medicare population, establishing similar eligibility criteria (upper age limit 77 years instead of 80). The health policies that resulted from these evaluations fostered the implementation of lung cancer screening programs.[21]

In March 2021, the USPSTF has issued an updated recommendation statement.[22] The updated eligibility criteria, based on additional modeling incorporating evidence generated since the 2013 statement, expands the prior criteria to include adults between 50 and 80 years of age who have a 20-pack-year smoking history and currently smoke or have quit within the past 15 years.[22]

In an effort to expand eligibility to others at risk for developing lung cancer who do not meet the above age and smoking history risk factors, some professional societies proposed eligibility criteria that include the presence of additional risk factors for lung cancer such as environmental exposures (e.g., radon, asbestos).[17,18] Another approach to identify individuals for screening that has been proposed is to estimate their risk of developing or dying from lung cancer, or their potential to benefit (gain life-years) from screening, by using validated prediction models (Table 109-2).[23–31] The variables included in risk models favor older individuals with more comorbidities and thus may result in the selection of individuals with a lower net mortality reduction benefit from screening. To mitigate this, estimates of life expectancy may be combined with risk models

TABLE 109-1 Trials That Evaluated CT Scanning for Lung Cancer Screening[2,3,9–15,49]

	Country	Recruitment Period	Sample Size	Screening Method	Interval	Inclusion Criteria Smoking Cessation	Lung Cancer Mortality RR/HR (95% CI)
NLST	United States	2002–2004	53,454	LDCT vs. CXR	Three annual screens	55–74 ≥30 pack-years <15 years	0.85 (0.75–0.96)
NELSON	Netherlands/ Belgium	2003–2006	15,822	LDCT vs. usual care	Four screens with different intervals: 1 year, 2 years, and 2.5 years	50–75 ≥15 cigarettes per day for ≥25 years or ≥10 cigarettes per day for ≥30 years ≤10 years	0.76 (0.61–0.94)
DLCST	Denmark	2004–2006	4104	LDCT vs. usual care	Five annual screens	50–70 ≥20 pack-years ≤10 years	1.03 (0.66–1.60)
MILD	Italy	2005–2011	4099	LDCT vs. usual care	Annual and biennial for 5 years	≥49 ≥20 pack-years ≤10 years	Annual: 2.48 (0.98–6.29) Biennial: 1.24 (0.42–3.70)
UKLS	United Kingdom	2011–2014	4055	LDCT vs. usual care	Single-screen LDCT	50–75 Predicted risk of lung cancer ≥5% ≤10 years	NR
LUSI	Germany	2007–2011	4052	LDCT vs. usual care	Annual screen for 5 years	50–69 ≥15 cigarettes per day for ≥25 years or ≥10 cigarettes per day for ≥30 years ≤10 years	0.74 (0.46–1.19)
ITALUNG	Italy	2004–2006	3206	LDCT vs. usual care	Annual screen for 4 years	55–69 ≥20 pack-years ≤10 years	0.70 (0.48–1.04)
Depiscan	France	2002–2004	765	LDCT vs. CXR	Three annual screens	50–75 ≥15 cigarettes per day for ≥20 years	NR
DANTE	Italy	2001–2006	2450	LDCT vs. clinical review	Annual screen for 4 years	60–74 >20 pack-years ≤10 years	1.01 (0.70–1.44)

CXR, chest x-ray; LDCT, low-dose computed tomography; NR, not reported.

or included in a model of benefit. The application of these models may improve the accuracy of selection of screening candidates and lead to greater equity in eligibility for lung cancer screening. It is important to note that the screening eligibility criteria recommended by the USPSTF, based on age and smoking history, are the criteria used for insurance coverage. In addition, the use of risk-based or life-gained models to identify those eligible for screening is more cumbersome and challenging to implement.

It is important to consider the presence of comorbidities that might limit an individual's life expectancy when offering screening. Screening should be discontinued once an individual develops a health problem that significantly limits life expectancy or the ability or willingness to have curative intent treatment.[4] The NLST and the NELSON trial enrolled healthier individuals than a real-world screening program might encounter.[2,3] The NLST did not include individuals with history of lung or other cancer within 5 years.[2] The NELSON trial had a longer list of exclusions: moderate or severe health problems and an inability to climb two flights of stairs; a body weight of more than 140 kg; current or past history of renal cell carcinoma, melanoma, or breast cancer; and diagnosis of lung cancer or treatment related to lung cancer within 5 years. In general, older patients with more comorbidities are at higher risk for harms related to screening, such as complications related to procedures needed to evaluate screen-detected findings. On an individual level, it is challenging to distinguish those who are likely to have a net benefit from LCS despite their comorbidities from those who are more likely to be harmed by screening.

MANAGEMENT OF SCREEN-DETECTED LUNG NODULES

In the NLST any noncalcified nodule measuring at least 4 mm in any diameter was classified as positive. Abnormalities such as adenopathy or pleural effusions could be classified as positive as well.[2] The trial radiologists reported the findings to participants and their health care provider. They also developed management guidelines, but a specific approach to the evaluation of nodules was not mandated. Among the potential harms related to screening, the management of screen-detected lung nodules poses the greatest risk of harm to the individuals being screened. It is important to standardize lung cancer screening results reporting and management recommendations to minimize harms from overimaging and potentially avoidable invasive testing when LDCT screening is implemented in clinical settings.

TABLE 109-2 Clinical Risk Prediction Models That Estimate the Risk of Developing Lung Cancer, Dying from Lung Cancer, or Gaining Life-years from Screening

Model	Estimation	Projection Period	Variables
Bach (2003)	Lung cancer risk	1–10 years	Cigarettes per day, duration of smoking, duration of quitting, age, asbestos exposure, gender
Spitz (2007)	Lung cancer risk	1 year	Emphysema, hay fever, family history of any cancer, family history of cancer related to smoking, exposure to asbestos, exposure to dust, smoking status, pack years, age quit smoking
LLP (2008)	Lung cancer risk	5 years	History of pneumonia, history of cancer, family history of cancer, exposure to asbestos, duration of smoking
Hoggart (2012)	Lung cancer risk	1–5 years	Smoking status, cigarettes per day, duration of smoking, years quit smoking

The American College of Radiology developed a tool called Lung-RADS that standardizes the reporting of screening findings and recommends an approach to nodule management based on nodule size and risk, with goals of minimizing testing for benign nodules, expediting treatment of malignant nodules, and facilitating monitoring for quality assurance.[32] Scans with no lung nodules or nodules with specific patterns of calcification (e.g., central, popcorn) are categorized as Lung-RADS 1. Noncalcified nodules detected are assigned a risk category (2–4) according to their average size, attenuation on LDCT (solid vs. nonsolid), evidence of stability or growth, presence of calcification, and location (e.g., perifissural). Category 4 is further divided in 4A “suspicious” and 4B “very suspicious.” Category 4X is assigned for nodules with additional features or imaging findings that increase the suspicion of malignancy. Solid lung nodules should be measured as the average of long- and short-axis diameter on the same sagittal, coronal, or transverse image. Measurement of part-solid nodules is based on the size of the solid component. The most recent version (version 1.1) incorporates volumetric analysis as well. Each category is associated with management recommendations. For example, a solid nodule that has an average diameter of 5 mm on the baseline scan would be categorized as Lung-RADS 2 (Fig. 109-1). The risk of malignancy of this nodule is less than 1% based on NLST data, and the recommendation would be to continue annual screening in 12 months. A solid nodule with an average size of 20 mm on the baseline scan would be categorized as 4B (risk of malignancy more than 15%), and the recommendation would be to consider a diagnostic CT scan, positron emission tomography (PET) scan, or tissue sampling.

Notably, Lung-RADS raised the size threshold for solid lung nodules to be labeled positive on the baseline scan to 6 mm from the 4-mm threshold used in the NLST.[2] The adoption of a larger size threshold helps decrease the false-positive rates at the expense of a small reduction in sensitivity. Lung-RADS also recommends the provider consider repeating LDCT 1 month later for new large nodules that develop on an annual screening study. These nodules would be categorized as Lung-RADS 4; however, they may be caused by infectious or inflammatory conditions and may decrease in size or resolve during short-term follow-up.

The main goals of the management of screen-detected lung nodules are to expedite the evaluation and treatment of malignant nodules, and to avoid unnecessary procedures for benign nodules. It is important that each screening program develops a system that ensures high-quality lung nodule management. This may include the documentation of management care pathways, the formation of a multidisciplinary team, and the development of a quality assurance process. Nodules may be managed by locally available resources (e.g., referring clinician or consultant) or by establishing connections with lung nodule management programs. The evaluation of concerning nodules, where invasive procedures are being considered, should start with an estimation of the malignancy risk based on clinical experience or by using a validated clinical prediction model. For example, the Brock model, derived from a lung cancer screening population, has been validated to have excellent discrimination with an area under the curve of more than 0.90 for all screen-detected nodules even when applied for nodules 10 mm or smaller in size.[33] This can be a helpful tool in clinical decision-making and can assist with patient communication.

POTENTIAL HARMS

There are several potential harms from LDCT screening. Harms include physical harms related to the evaluation of screen-detected findings, psychological distress associated with knowledge of the results, overdiagnosis and overtreatment, and the risks related to radiation exposure.

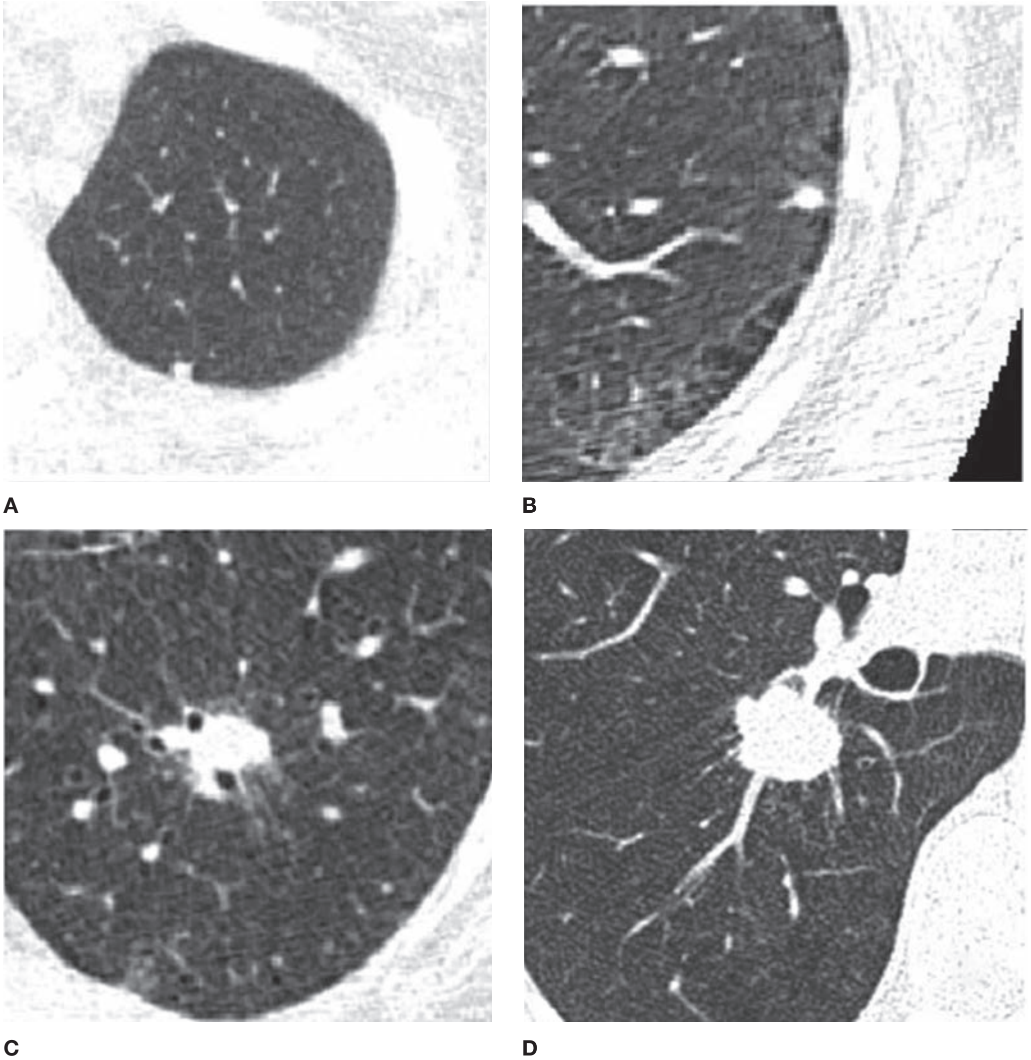

Figure 109-1 Examples of nodules and their Lung-RADS classification. **A.** Category 2: left upper lobe nodule with average size of 5 mm. Recommendation was to continue annual screening. **B.** Category 3: left upper lobe nodule with average size of 6.7mm. Recommendation was to follow in 6 months with LDCT. **C.** Category 4A: left lower lobe nodule with average size of 9.5 mm. The nodule was followed with LDCT after 3 months, which showed resolution of the nodule. It was likely an inflammatory nodule. **D.** Category 4B: spiculated right lower lobe nodule with average size of 21 mm (21 mm × 21 mm). The nodule was evaluated with a PET scan and diagnosed as squamous cell carcinoma by bronchoscopy. The tumor was treated with radiation ablative therapy.

Lung nodules, commonly found on screening LDCT, may prompt evaluation with additional chest imaging or invasive procedures for tissue diagnosis such as bronchoscopy, transthoracic needle biopsy, or surgical resection. In the NLST, 96% of positive scans (nodules ≥4 mm) were not malignant and 20% of all surgical resections were performed for nodules ultimately proven to be benign.[2] The frequency of major complications and death from a diagnostic evaluation of an LDCT screen-detected finding was 33 per 10,000 individuals and 5 per 10,000, respectively.[2]

Lung cancer screening may also cause psychological harms. Being screened for lung cancer may lead to anxiety, and learning that the scan detected a nodule may cause or increase psychological distress.[34,35] Although the early psychological impact may be significant, it is often transient and does not adversely impact longer-term quality of life.[34,35] Preparing those being screened for the possible results during a shared decision-making visit, prior to the screening LDCT, may help to mitigate the distress. A standardized approach to managing screen-detected nodules should be flexible enough to incorporate a patient's concerns and values in the management plan.

Overdiagnosis and overtreatment refer to the identification and management of a lung cancer that would not have impacted the well-being or survival of the patient if never detected. Some lung cancers are so indolent that they may never affect quality of life or be a cause of death. Overdiagnosis can also occur if a patient with severe comorbid conditions dies from one of these conditions before even a non-indolent lung cancer would have affected them. The NLST estimated overdiagnosis rates to be around 18% in the population studied with their protocol.[2]

The average effective dose of radiation from a screening LDCT is 4 to 5 times lower than a diagnostic chest CT scan (1.5 vs. 8 mSv).[36,37] The risks of developing a radiation-related cancer are felt to be low. The risk may be influenced by the age at which screening started, the sex of the patient, the numbers of LDCT scans, and exposure to other sources of radiation related to the evaluation of screen-detected findings (e.g., diagnostic imaging). It is challenging to quantify the effects of radiation exposure. One study estimated that 1 in 2500 patients screened may die of radiation-related malignancy from the cumulative radiation over the 3 years of LDCT screening in NLST.[37] Another study estimated a risk of 0.05% of developing a serious malignancy after 10 years of screening with radiation dose 40% lower than that used in NLST. This translates theoretically to 1 radiation-induced cancer for every 108 lung cancers detected over 10 years.[38]

NON-NODULE FINDINGS

Incidental pulmonary and extrapulmonary findings are common on screening LDCT.[39] Their prevalence can be as high as 94% depending on how they are defined and whether they are routinely described on the scan report. The most frequently reported findings are in the respiratory and cardiovascular systems. In a cohort of screening individuals, incidental pulmonary and cardiovascular findings were present in 69% and 67% of the scans, respectively.[39] Emphysema and coronary calcifications were the most common findings. Most non-nodule incidental findings are not clinically significant. In a systematic review, 14% of scans had findings that merited some form of additional evaluation.[40] Serious diagnoses can be found including severe coronary artery disease that requires intervention, and extrapulmonary malignancies.[39]

The potential to identify significant non-lung nodule findings should be discussed during shared decision-making visits considering their high prevalence. Each screening program should develop an approach to their management. Clinical guidelines exist to help establish an approach to the most common findings.[41,42]

IMPLEMENTATION OF LUNG CANCER SCREENING PROGRAMS

Lung cancer screening requires a dedicated multidisciplinary team and effective communication among all stakeholders. A high-quality screening program requires a robust infrastructure to meet regulatory mandates and clinical demands. There are multiple aspects of the screening process that a program needs to orchestrate, including the selection of screen-eligible individuals, shared decision-making, LDCT performance and reporting, management of screen-detected findings, provision of smoking cessation guidance, and tracking compliance with annual screening.

The adoption of lung cancer screening in the United States is growing, but it remains low.[43] Programs should educate clinicians and the general public about the eligibility criteria for lung cancer screening. There are a spectrum of program designs ranging from decentralized to completely centralized. In decentralized programs the referring provider is responsible for all aspects of the individual's care, from identifying them as screening candidates, engaging in shared decision-making, managing the screening findings, assisting with smoking cessation, and ensuring compliance with annual screening. The screening program can develop and provide resources for the provider to assist with these tasks. In a centralized program, providers make a referral to the program, and the screening program is primarily responsible for most of these functions. The screening program communicates patient management plans with the referring provider.

Given that there are potential benefits and harms from lung cancer screening and that those eligible are by definition otherwise feeling well, it is important that programs engage in shared decision-making with those considering screening. In addition, a dedicated visit for shared decision-making is currently mandated by CMS before the baseline screen.[21] The goal of shared decision-making is to inform individuals about the tradeoffs of screening versus not screening and to help them make a choice that is aligned with their preferences and values. The visit is an opportunity for patients to learn about their individual risk of developing lung cancer and the potential benefits and harms from screening. There is no mandated format for the visit, and the most effective method has not been determined. Risk or benefit prediction calculators and decision aids are helpful tools.[44] The net benefit of screening varies based on the risk of developing lung cancer and the individual's other health issues. By understanding these variables it may be possible to shape the shared decision-making discussion based on the estimated net benefit of screening.

The LDCT scans should be acquired with the use of multidetector helical CT scanners with at least 16 detectors.[16] The acquisition variables should maintain a CT dose–volume index ≤3.0 mGy for average-size patients.[2] This leads to an average effective dose of 1.5 mSv, more than 5 times lower than the effective dose with diagnostic CT scans of the chest.

FUTURE DIRECTIONS

The emergence of lung cancer screening as standard of care represents a major advance in mitigating lung cancer mortality. There are opportunities to optimize the balance of benefits and harms of lung cancer screening. Doing so will allow for the expansion of eligibility, providing access to screening for more at risk individuals, and improving equity in the provision of this service. The incorporation of risk and benefit prediction tools into screen-eligibility criteria may help with this goal. Early-detection molecular biomarkers from a variety of sources have been studied including sputum, saliva, nasal and bronchial airway epithelial cells, exhaled breath, blood, and urine.[45] Advances in the development and validation of molecular biomarkers capable of identifying those at high risk of developing lung cancer, or those that have an early stage lung cancer, may improve the efficiency of candidate selection for screening, expand access to screening, and minimize the potential harms by accurately characterizing screen-detected nodules.[45]

Automated systems using artificial intelligence (AI) may increasingly assist in the management of lung nodules detected by screening. Commercially available software is already in clinical use for automated nodule detection and size measurement.[46] AI tools help radiologists identify more nodules and improve the efficiency of reading scans.[47] These tools may assist with high-quality image interpretation in areas where well-trained radiologists are scarce. In addition to detection and measurement, advances have been made in nodule characterization and risk classification. A deep learning algorithm with an end-to-end approach with both detection and lung cancer risk categorization showed promising results, with the potential to reduce false-positive and false-negative results compared with radiologists.[48] Population health management systems will assist with results tracking and the ability of programs to track and encourage compliance with screening recommendations. Advances in shared decision-making processes, smoking cessation assistance, and the expansion of access to high-quality screening programs will improve access to screening that optimizes the net benefit for individuals and for the population.

CHAPTER 110

Approach to the Patient with Pulmonary Nodules

Moiz Salahuddin
David E. Ost

INTRODUCTION

The radiographic finding of a pulmonary nodule, formerly known as a *coin lesion*, has long challenged the clinician. At the heart of the dilemma, the question remains unchanged: "Is it malignant or benign?" When faced with a pulmonary nodule, the clinician and the patient usually have one of three choices: (1) observe it with serial chest computed tomography (CT), (2) perform additional diagnostic tests, or (3) remove it surgically.

The proper choice depends on epidemiology, radiographic appearance, assessment of surgical risk, and patient preferences. For malignant lesions, early surgical resection still represents the best chance for cure. On the other hand, unnecessary resection of benign nodules exposes patients to the morbidity and mortality of a surgical procedure. The aim of this chapter is to review what is known about the pulmonary nodule to formulate a diagnostic approach to this often controversial problem. The goal will be to arrive at a systematic approach that will promptly identify and bring to surgery all patients with operable malignant nodules while avoiding thoracotomy in patients with benign nodules. To do this, we need to have a clear definition of pulmonary nodules, information on their incidence and prevalence, the causes of malignant and benign nodules, the available imaging techniques, a method of estimating the probability of cancer, the strengths and weakness of serial CT imaging versus different biopsy techniques, and the impact of surgical risk and comorbidities on diagnostic strategies. These various considerations can then be integrated into an algorithm providing a unified approach to diagnosis and management.

DEFINITION

Pulmonary nodules should be characterized on the basis of number, size, and density as determined by CT. A solitary pulmonary nodule is defined as a single discrete pulmonary opacity that is surrounded by normal lung tissue that is not associated with adenopathy or atelectasis.[1,2] Previously there was controversy as to what constituted the upper size limit for defining a solitary pulmonary nodule. Some early series included lesions up to 6 cm in size.[3,4] However, it is now recognized that lesions larger than 3 cm are almost always malignant, so current convention is that solitary pulmonary nodules must be 3 cm or less in diameter.[5–7] Larger lesions should be referred to as pulmonary masses and should be managed with the understanding that they are most likely malignant; prompt diagnosis and resection is usually advisable.[7]

The term *solitary pulmonary nodule* was originally used when most nodules were detected incidentally by chest radiography. Today, most nodules are detected by CT, which greatly enhances nodule detection and characterization. However, we now recognize that many nodules that would have been characterized previously as "solitary" by chest radiograph are actually not solitary, since there may be other small nodules present. Thus, the classic definition of pulmonary nodules needs to be revised to take into account data from more recent CT-based studies.[1,7] As such, the term *solitary* should not be used for nodules accompanied by additional nodules or associated findings, or for nodules not completely surrounded by aerated lung.

CT has also increased awareness of subcentimeter nodules, which are defined as those ≤8 mm in diameter.[1,8–10] Subcentimeter nodules may be spherical or nonspherical, and malignant nodules may have either shape.[10] CT has also led to a more precise and nuanced classification of nodules according to their density. Nodules may have a pure solid appearance, a pure ground-glass appearance, or a mixed ground-glass and solid appearance. These characteristics can be used to help estimate the probability of cancer in the nodule.

INCIDENCE AND PREVALENCE

The incidence of pulmonary nodules and the probability of malignancy in those nodules vary widely, depending on the patient population; thus, many case series may not be directly comparable. This is a critical distinction when reviewing the literature. It is essential, therefore, to consider the clinical context that led to nodule detection. Surgical case series, in which the denominator consists entirely of resected lung nodules, have a much higher prevalence of malignancy compared with studies that include all nodules detected by chest radiograph or CT. Note that the prevalence of cancer seen in these surgical case series is not the same as the pretest probability of cancer for a newly identified lung nodule. Cancer prevalence in surgical series is high because the population being studied consists entirely of patients in whom the clinical suspicion of cancer based on prior testing has been deemed high enough to warrant the risk of surgery. Nodules unlikely to be malignant tend to be excluded from surgical case series. Given these limitations, surgical case series data can still be useful to gain insight into the factors that impact the probability of cancer.

The frequency with which a pulmonary nodule is identified on chest radiography is on the order of 1 to 2 per 1000 chest radiographs.[11] Most of these are clinically silent, and about 90% are noted as an incidental finding on radiographic examination. Younger patients from areas where granulomatous diseases such as tuberculosis, histoplasmosis, and coccidioidomycosis are endemic can be expected to have a lower malignancy rate. In an Air Force Medical Center study from Illinois of 137 patients, only 22 (16%) had a malignancy.[12] Granulomas were diagnosed in 103 (75%) patients; 53 of them were attributable to histoplasmosis endemic to the area. Most of these patients (77%) were under age 45, and no malignant nodules were diagnosed in patients less than 35 years of age. This series predated the use of chest CT.

Importantly, the incidence of nodules and the probability of malignancy in the nodules are very different in more recent studies of low-dose CT screening for lung cancer among high-risk patients than in surgical case series. The prevalence of noncalcified nodules in observational studies of low-dose CT screening ranges from 13% to 51%.[13–15] Among nodules that are identified on the first screening study, the prevalence of cancer ranges from 3% to 12%.[16] On follow-up CT imaging of the same population (i.e., incidence screens), the probability of new noncalcified nodules has varied widely, from 2.5% to 13%. The probability of cancer in these incidence nodules has varied from 5% to 23%.

MALIGNANT PULMONARY NODULES

Risk factors for malignancy have been identified from studies of pulmonary nodules and include patient age, smoking history, nodule size, and prior history of malignancy. Age is one of the most consistent risk factors. In a series of 370 resected indeterminate solitary pulmonary nodules, the incidence of malignancy increased from 63% for patients age 45 to 54 to 74% for ages 54 to 64 and continued to rise with age to 96% for those above the age of 75.[17] Since this was a surgical case series, in which the denominator consists of resected lung nodules, the prevalence of malignancy is much higher compared with studies of nodules detected by chest radiograph or during lung cancer screening. These findings correlate with those of previous studies, which also show that malignancy is very rarely found in patients under the age of 35.[12,18,19]

Smoking is closely correlated with the development of lung cancer, particularly squamous and small cell carcinoma. The Surgeon General's report of 1964 and subsequent studies have demonstrated that the risk of lung cancer increases with the duration of smoking and the number of cigarettes smoked. Average smokers have about a 10-fold risk and heavy smokers a 20-fold risk of developing lung cancer when compared with nonsmokers. Smoking is responsible for about 85% of the cases of bronchogenic carcinoma. Cessation of smoking will reduce this risk after 10 to 20 years, but it now appears that former smokers have a slightly higher risk of cancer throughout their lifetimes.

Nodule size is closely correlated to risk of malignancy. Several series have demonstrated an increased incidence of malignancy with increasing nodule size. Lesions larger than 3 cm (i.e., pulmonary masses) will be malignant 80% to 99% of the time. In seven studies of nodules detected in lung cancer screening trials, the prevalence of malignancy was 0% to 1% in patients with nodules <5 mm in diameter, 6% to 28% for 5- to 10-mm nodules, 33% to 64% for 11- to 20-mm nodules, and 64% to 82% for nodules measuring >20 mm.[12,17,20–23]

Primary bronchogenic carcinoma is the most common malignant tumor that presents as a pulmonary nodule.[5,17,21,24] Histologically, adenocarcinoma and squamous cell carcinoma make up the majority; of the two, adenocarcinoma is the more common (Table 110-1). Of note, tumors that used to be called bronchioloalveolar cell carcinoma (BAC) have now been reclassified and the term *adenocarcinoma in situ* is used for BAC tumors once they have been confirmed by surgical resection. Small-cell carcinoma presenting as a solitary pulmonary nodule is rare. Other rare primary lung tumors that may present as solitary pulmonary nodules are bronchial carcinoids, lymphomas, hemangioendotheliomas, and sarcomas.

Metastases may present as solitary pulmonary nodules in patients who have known primary malignancies or in whom the presence of primary malignancy is unknown. In up to 40% of such patients, who manifest only a single nodule on chest radiograph, CT scan may show other nodules that are not disclosed by plain chest radiograph.[25,26] Even though a lesion is solitary, 33% to 95% of nodules in patients with an established diagnosis of cancer will be malignant.[27–31] The most common histologic types of metastatic nodules are adenocarcinomas of the colon, breast, and kidney; head and neck tumors; sarcoma; and melanoma. Because of the high likelihood of malignancy, a nodule in a patient with an established diagnosis of cancer should be treated differently from other solitary nodules. Assuming no other obvious metastatic spread, one should consider proceeding directly to biopsy. Even in the presence of a known lung cancer, some of these nodules may represent a second primary pulmonary malignancy that is similar in histologic appearance. Immunohistochemistry and other confirmatory marker studies may be indicated to determine the nature of the nodule. A solitary pulmonary nodule in a patient with a history of solid organ malignancy should be considered for resection as long as there is no other evidence of recurrent or metastatic disease.

BENIGN PULMONARY NODULES

Benign pulmonary nodules are more common in the young and in nonsmokers. Causes include benign tumors such as hamartomas, both infectious and noninfectious granulomas, vascular lesions, and rare miscellaneous conditions (Table 110-1).

TABLE 110-1 Differential Diagnosis of Solitary Pulmonary Nodules

Malignant Tumors
- Bronchogenic carcinoma (adenocarcinoma, large cell, squamous, small cell)
- Carcinoid
- Pulmonary lymphoma
- Pulmonary sarcoma
- Plasmacytoma
- Solitary metastases (colon, breast, kidney, head and neck, germ cell, sarcoma, thyroid, melanoma, others)

Benign Tumors
- Hamartoma
- Adenoma
- Lipoma

Infectious Granulomas
- Tuberculosis
- Histoplasmosis
- Coccidioidomycosis
- Mycetoma
- Ascaris
- Echinococcal cyst
- Dirofilariasis (dog heartworm)

Noninfectious Granulomas
- Rheumatoid arthritis
- Granulomatosis with polyangiitis (formerly known as Wegener granulomatosis)
- Sarcoidosis
- Paraffinoma
- Others

Miscellaneous
- Bronchiolitis obliterans organizing pneumonia
- Abscess
- Silicosis
- Fibrosis/scar
- Hematoma
- Pseudotumor
- Spherical pneumonia
- Pulmonary infarction
- Arteriovenous malformation
- Bronchogenic cyst
- Amyloidoma

Hamartomas are the most common benign tumors presenting as solitary pulmonary nodules. They are believed to be developmental malformations composed mainly of cartilage, fibromyxoid stroma, and adipose tissue. A review of 6 series with 3802 resected solitary pulmonary nodules found that 5% were hamartomas.[12,17,19,32–34] In a series of 215 hamartomas resected at the Mayo Clinic, the peak incidence was in the seventh decade of life; male-to-female ratio was 1:1; and the average size was 1.5 cm, although some were as large as 6 cm.[35] Most hamartomas were asymptomatic (97%), and 17% were noted to grow slowly on serial radiographic examination. They may be identified radiographically by a pattern of "popcorn" calcification, which is often intermixed with areas of low attenuation on CT

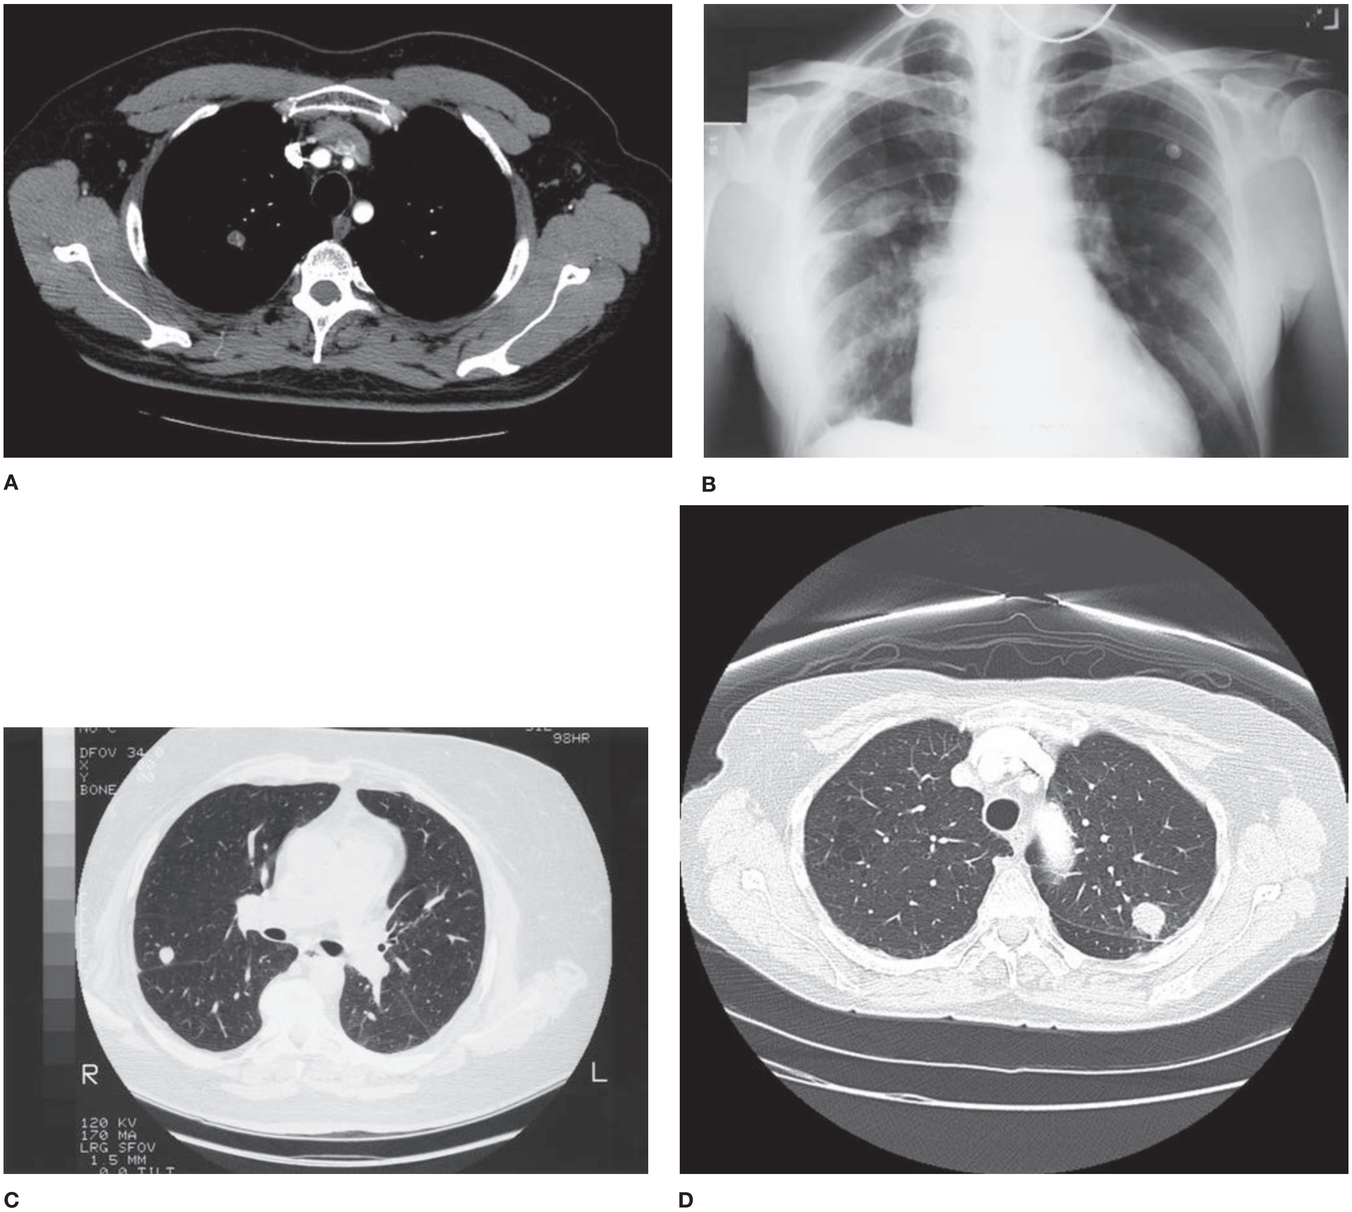

Figure 110-1 Benign pulmonary nodules and their radiographic patterns: **A.** Hamartoma with fat density within the nodule. **B.** Pseudotumor due to fluid in a fissure, the result of both pleural disease and fluid overload, has the appearance of a pulmonary mass. **C.** Noncontrast CT shows a round 1-cm nodule, with relatively high radiographic density, proven on resection to be a granuloma. **D.** Nodule with smooth border, diagnosis histoplasmosis.

scan representing fat deposits within the nodule. CT appearance is diagnostic in about 50% of hamartomas, with the finding of fat attenuation between −40 to −120 Hounsfield units (Fig. 110-1).[36]

Infectious granulomas make up more than 90% of all benign nodules. They arise as a result of healing after infection from a variety of organisms. The offending agents will vary, depending on geographic location. Among the most common causes are histoplasmosis, coccidioidomycosis, and tuberculosis. Other, less common infectious causes of infectious granulomas are dirofilariasis (dog heartworm), mycetoma, echinococcal cyst, and ascariasis. A history of exposure is important in establishing a possible infectious origin. Clues such as tuberculosis exposure history and skin test results, prior travel history, places of residence, occupation, and pets may be invaluable in some instances.

A variety of inflammatory diseases can also cause benign pulmonary nodules. Noninfectious granulomas sometimes present as pulmonary nodules in systemic diseases such as sarcoidosis, in which nodules are not invariably accompanied by hilar adenopathy. Necrobiotic nodules are pulmonary nodules with granulomatous inflammation and central necrosis on histopathology. These nodules can be seen in patients with active rheumatoid arthritis and inflammatory bowel disease. In rheumatoid arthritis, patients may also have concurrent subcutaneous nodules. Granulomatosis with polyangiitis (formerly known as Wegener granulomatosis) can also present with pulmonary nodules, which are often cavitary. In such cases there are usually multiple nodules and there may be concurrent renal or sinus disease.

Miscellaneous causes of benign pulmonary nodules include rounded pneumonia, pseudotumor (which represents fluid in an interlobar fissure) (Fig. 110-1), hematomas after thoracic trauma or surgery, and fibrosis or scars resulting from the resolution of infectious or inflammatory process. Rarer conditions presenting as pulmonary nodules include silicosis, bronchogenic cyst, amyloidosis, pulmonary infarct, and arteriovenous malformations.

Arteriovenous malformations may grow slowly and have a characteristic appearance on contrast-enhanced CT scan, with identification of afferent and efferent vessels emanating from and heading toward the hilum, respectively.

IMAGING TECHNIQUES

Imaging techniques are often helpful in distinguishing benign from malignant causes of pulmonary nodules, and as such they play a key role in their evaluation and management. During the last decade, rapid advances in both CT and positron emission tomography (PET) have dramatically changed the diagnostic approach to pulmonary nodules. However, this does not mean that these techniques should be used indiscriminately. Cost-effective strategies to manage pulmonary nodules require that we understand the performance characteristics, strengths, and weaknesses of each of these technologies, so that they can be applied properly.[37] The primary technologies that need to be considered are plain chest radiography, CT, and PET (Chapter 28).

■ Plain Chest Radiography

Many pulmonary nodules are discovered on routine plain chest radiograph while asymptomatic. Nodules are usually identifiable on chest radiograph by the time they are 0.8 to 1 cm in diameter, although nodules 0.5 to 0.6 cm can occasionally be seen.[11] Most will be identified on posteroanterior (PA) projection, but some will be seen only on lateral projection, so standard PA and lateral chest radiography should be obtained whenever possible. When a nodule can be seen only on one projection, the clinician should question whether it is truly in the lung parenchyma. Structures overlying the lungs, such as leads used for cardiac monitoring, nipple shadows, breast calcifications, skin lesions, and rib lesions can all mimic a pulmonary nodule, as can pulmonary vessels viewed end-on. If in doubt, a CT should be obtained. Once it has been ascertained that a true nodule exists, the first step is to make every effort to obtain previous radiographs for comparison. A solid nodule that has remained stable with no increase in size for 2 years by CT is very likely benign and warrants no further investigation. Similarly, a nodule that was not present on a comparable radiograph within the past 2 months is unlikely to be malignant, having grown so rapidly.

■ Computed Tomography

Chest CT should be part of the evaluation of all lung nodules, either alone or as part of a combined PET-CT. As with chest radiography, comparison with prior CT imaging is critical, since it can provide an estimate of the growth rate over time. CT can pinpoint the exact location of the nodule and provide three-dimensional images of the lesion. Thin-section high-resolution CT can better define the borders and the nodule's relation to adjacent structures, such as vessels and the pleura.[23,38] CT is also more sensitive than standard chest radiographs in detecting calcifications and can quantify calcification in nodules even when they are not readily visible to the naked eye.[23,39] Nodules with higher radiographic density are more likely to be benign (Fig. 110-1).

Calcification is generally an indication of benignity in a pulmonary nodule. Infectious granulomas tend to calcify with central, diffuse, or stippled patterns (Fig. 110-2). Laminar or concentric calcification is characteristic of granulomas caused by histoplasmosis. A popcorn calcification pattern is typically seen in hamartomas and when coupled with fat density within the same nodule is highly specific. Calcification is seen in 6% to 14% of malignant nodules, with a punctate or eccentric pattern. Benign patterns of calcification (central, diffuse, laminar, or popcorn) are very rare in malignant nodules. In one study of 1267 solitary pulmonary nodules, only 7 malignant nodules (0.6%) had a benign calcification pattern.[40] Most nodules with a benign calcification pattern can be observed with serial CT scans.

The edge characteristics of nodules can also offer insight into whether or not a lesion is malignant. Benign lesions are often well circumscribed with a round appearance, whereas malignant nodules tend to have irregular or lobulated borders (Fig. 110-3). CT imaging characteristics that suggest malignancy include spiculated margins (likelihood ratio [LR], 5.5)[23,24,38] and pleural retraction (LR, 1.9). Lobulated margins (LR, 1.1) are associated with malignancy, but the predictive value is low.[41] Other patterns that have been reported to be associated with malignancy include vascular convergence (presence of vessels abnormally angled toward the nodule),[42] a dilated bronchus leading into the nodule,[43] pseudocavitation ("bubbly" appearance thought to represent air bronchiolograms),[38] and true cavitation associated with a thick and irregular wall.[44] Squamous cell cancers can lead to a cavitary pulmonary nodule. Up to 95% of cavitary nodules with a wall thickness greater than 15 mm are malignant, and 92% of cavitary nodules with a wall thickness less than 5 mm are benign.[45] However, none of these radiographic signs is entirely specific for malignancy. Malignancy is somewhat less likely if an air bronchus sign is present although its predictive value is low. An air-bronchus sign can be seen in primary pulmonary lymphoma, but this is a very rare disease, accounting for less than

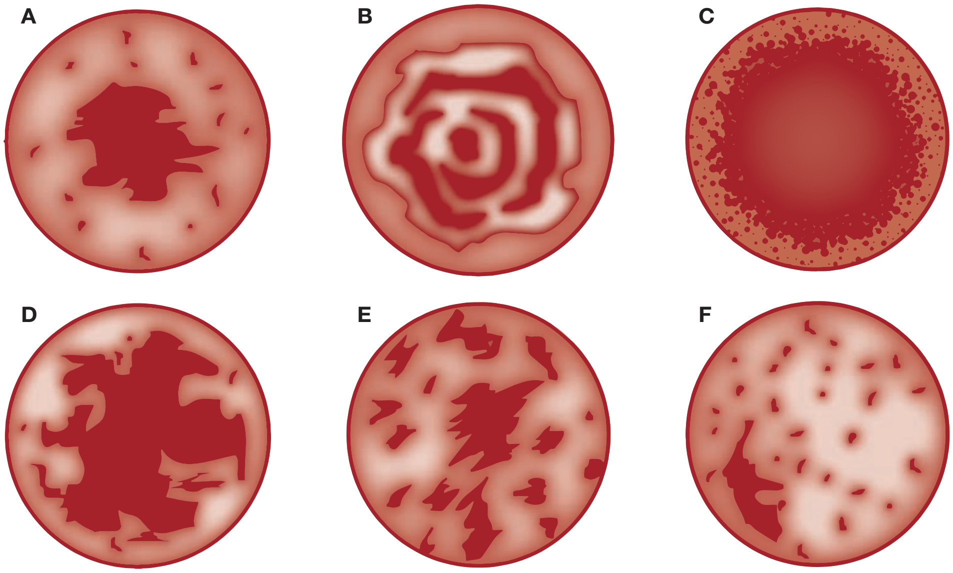

Figure 110-2 Patterns of calcification in nodules. **A.** Central. **B.** Laminated. **C.** Diffuse. **D.** Popcorn. **E.** Stippled. **F.** Eccentric. Patterns A, B, C, and D generally indicate a benign process; E and F suggest malignancy. *(Data from Lillington GA. Management of solitary pulmonary nodules. Dis Mon. 1991;37(5):271–318.)*

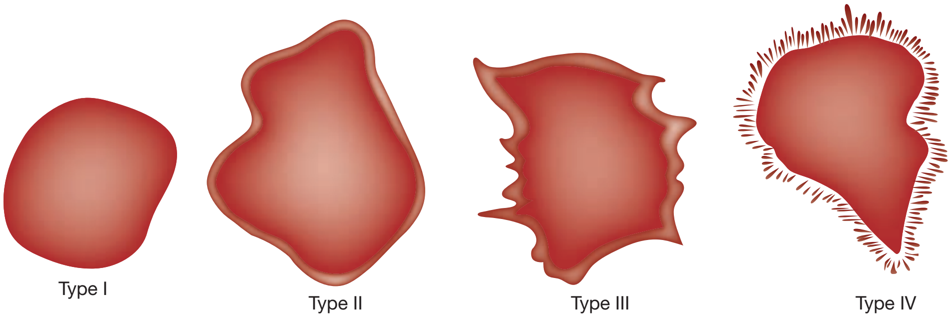

Figure 110-3 Characteristic appearance of nodule edges. Type I is sharp and smooth, type II is lobulated, type III has irregular undulations, and type IV is grossly irregular with many spiculations. *(Data from Siegelman SS, Khouri NF, Leo FP, et al. Solitary pulmonary nodules: CT assessment. Radiology. 1986;160(2):307–312.)*

1% of all lung cancers. Malignancy is much less likely if a nodule has smooth or polygonal margins (LR, 0.2).[46]

Rapid advances in CT technology have also led to more precise characterization of the density of lung nodules. It is now appreciated that nodules may be characterized as solid, partly solid, or pure ground-glass opacities (defined as focal densities in which underlying lung morphology is preserved) (Fig. 110-4). This is particularly useful for categorizing small nodules (<1 cm) since these categories can help to distinguish benign from malignant nodules. The percentage of pure ground-glass opacities that are malignant varies significantly in the literature, from 18% to almost 60%.[47–49] For subcentimeter nodules, the likelihood of malignancy is similarly high in partly solid lesions, but much lower (<10%) in solid nodules.[47,49]

Ground-glass nodules may represent either atypical adenomatous hyperplasia (AAH) or adenocarcinoma in situ (formerly BAC).[42,50–56] In contrast, partly solid or solid nodules usually represent adenocarcinoma but can also be caused by squamous cell carcinoma or small cell carcinoma. When pure ground-glass opacities start to grow and become more solid, demonstrating a replacement growth pattern, this should be considered highly suspicious for adenocarcinoma.[1,57,58] Of note, observed growth rates are often very slow for malignant ground-glass opacities, intermediate for partly solid nodules, and relatively fast for solid nodules.[59]

The superior resolution of multidetector scanners has also facilitated the development of volumetric CT. Volumetric CT may allow growing lesions to be identified earlier than conventional transverse CT. Preliminary studies demonstrated that three-dimensional volume analysis enabled tumor growth to be detected in 5-mm diameter nodules as early as 30 days after the initial CT.[60,61] Volumetric CT was successfully used to guide evaluation of small lung nodules in the NELSON trial.[8,62] In that trial, the investigators used serial volumetric CT measurements to calculate the doubling time of indeterminate lung nodules. CT volume doubling time of <400 days or a new solid component in a previously nonsolid nodule was defined as positive.[8] Follow-up imaging could detect growth as early as 6 weeks after imaging of an indeterminate nodule. The second-round screening to detect lung cancer had a sensitivity of 96.4%, specificity of 99.0%, positive predictive value of 42.2%, and negative predictive value of 99.9%.

A complementary technique is dynamic CT, which uses iodinated IV contrast to look for enhancement of nodules.[63] Although malignant nodules enhance more than benign ones, benign lesions, such as hamartomas and tuberculomas, also may enhance. Median sensitivity and specificity for detecting malignant nodules from seven studies in a systematic review were 96% and 75%, respectively.[20,63–69] In a multicenter trial using dynamic CT, the negative predictive

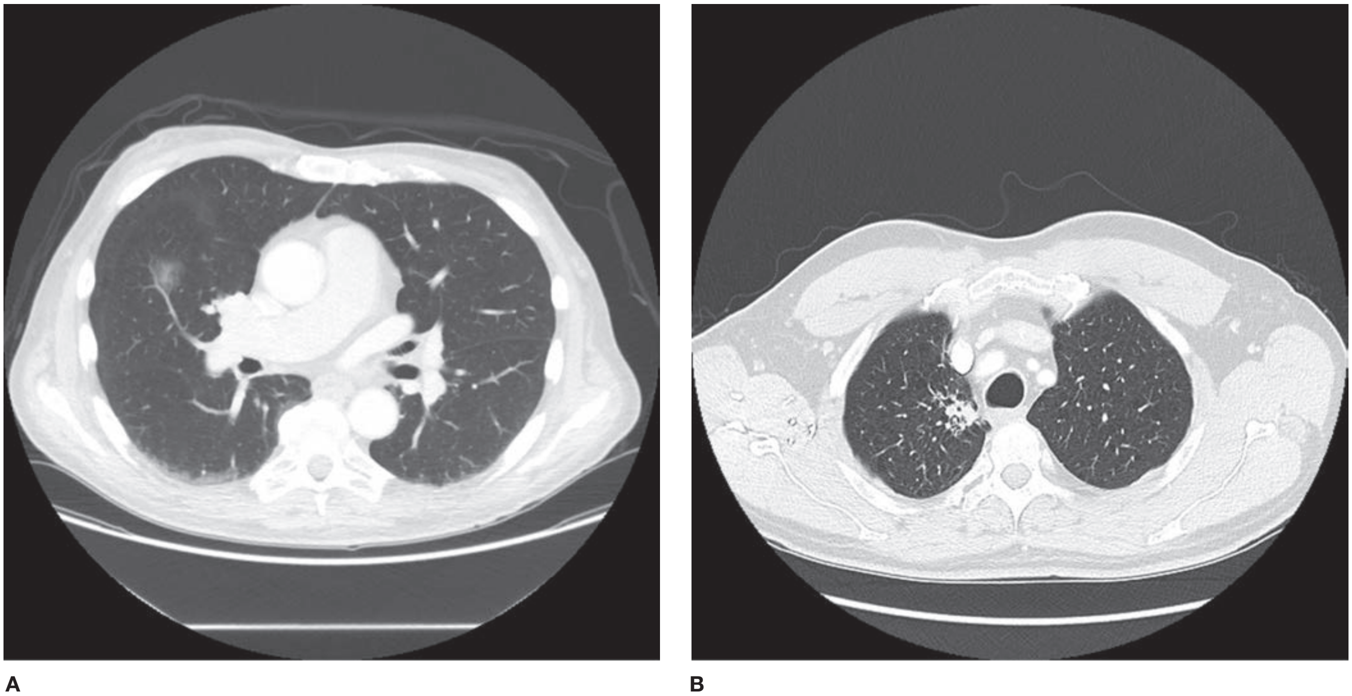

Figure 110-4 Malignant nodules with different densities and borders: **A.** Ground-glass nodule, right middle lobe, diagnosis adenocarcinoma in situ. **B.** Air bronchogram with semisolid nodule, diagnosis adenocarcinoma. *(continued)*

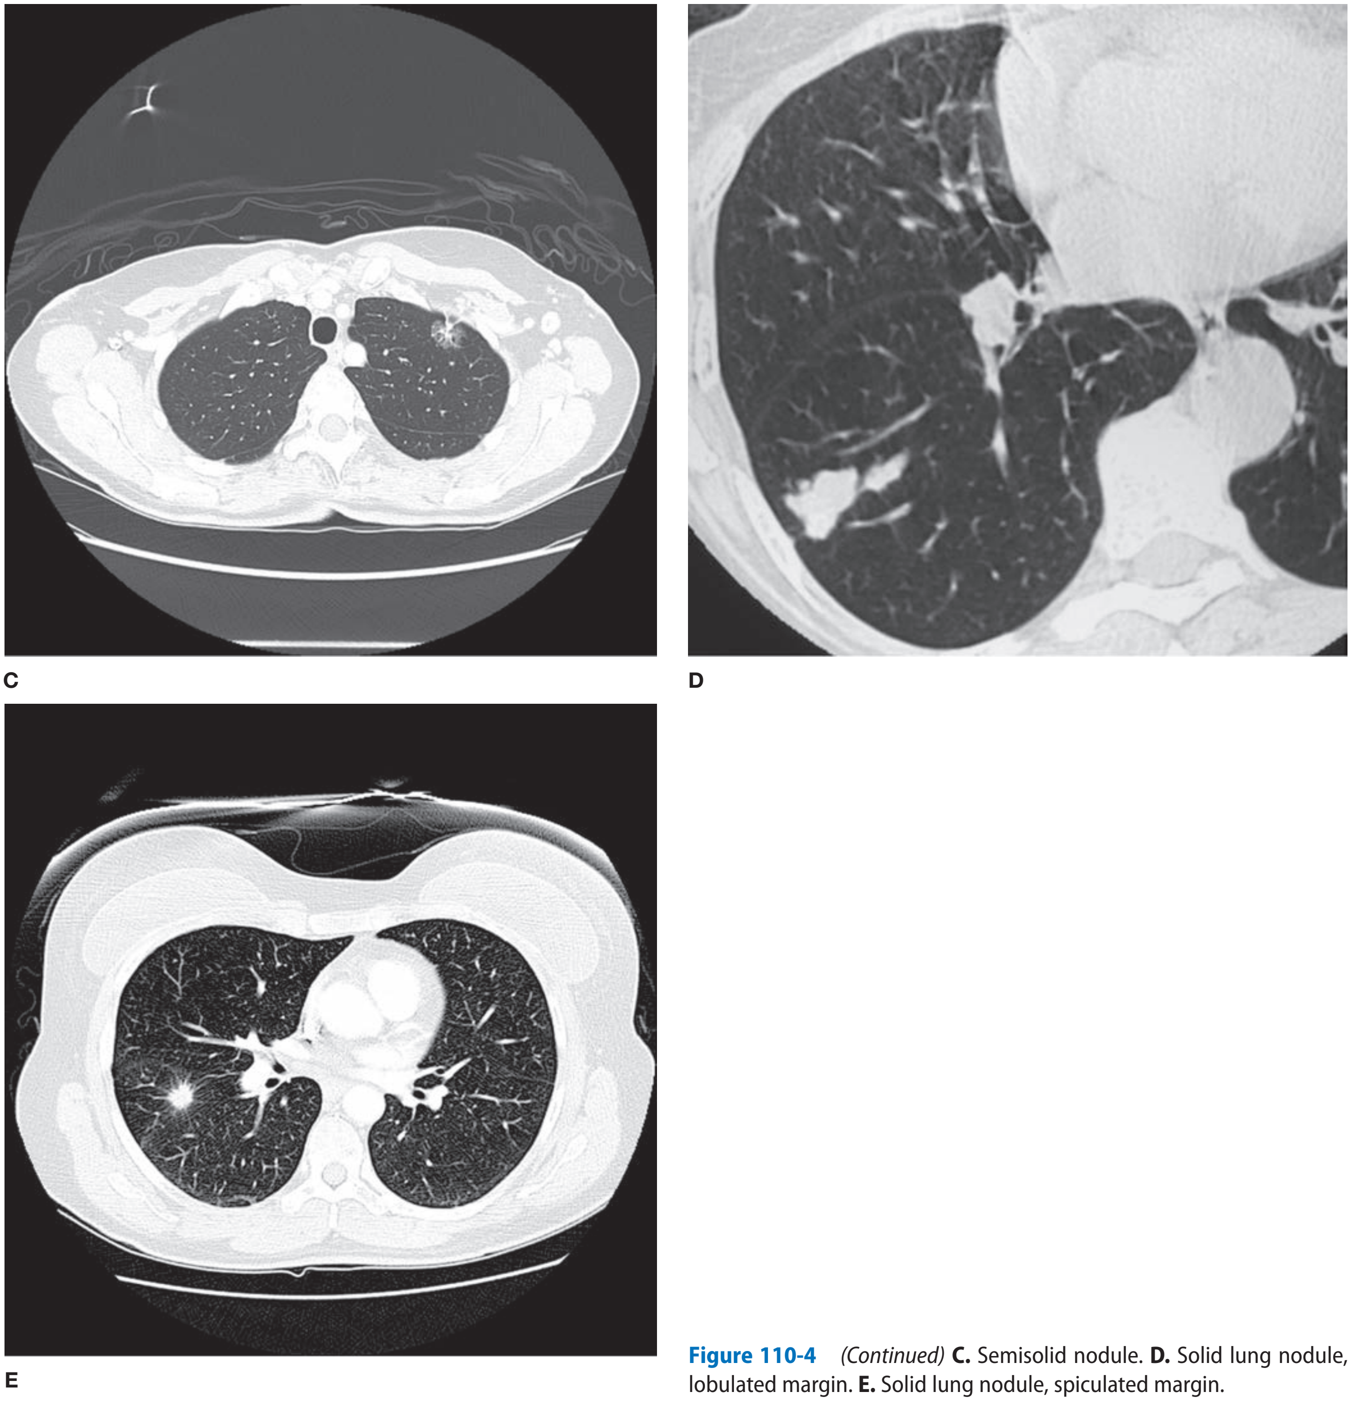

Figure 110-4 *(Continued)* **C.** Semisolid nodule. **D.** Solid lung nodule, lobulated margin. **E.** Solid lung nodule, spiculated margin.

value was 97%. However, lack of specificity has limited the utility of this test, since it cannot reliably distinguish between malignant and active inflammatory or infectious nodules. As a result, few centers at the present time are using this approach.

■ Positron Emission Tomography (PET)

PET can be used to help differentiate between malignant and benign nodules. PET takes advantage of the fact that tumor cells have increased glucose uptake and metabolism. A D-glucose analogue labeled with a positron-emitting fluorine-18 radioisotope (FDG) is injected into the patient, and uptake by the nodule is then measured. Malignant nodules have a higher uptake of FDG. Sensitivity of PET in systematic reviews has ranged from 87% to 95%.[2,61,70] Integrated PET-CT scanners combine the CT and FDG imaging gantry, allowing more precise anatomic localization of areas of FDG uptake than dedicated PET imaging alone.[71–73] PET imaging also provides useful information regarding lung cancer staging, since it will occasionally detect unsuspected regional lymph node and distant metastases.[74]

It is important to recognize that most studies of PET have used a single threshold level for discriminating malignant from benign nodules, typically a standard uptake value (SUV) of 2.5.[2,74] However, PET images actually provide a range of possible results, depending on the amount of uptake in the nodule compared with that of the mediastinal blood pool. In a study of 344 patients undergoing PET-CT, the likelihood ratios for benign, probably benign, indeterminate, probably malignant, and definitely malignant were 0.03, 0.15, 1.01, 3.2, and 9.9, respectively.[75] When FDG uptake was slightly greater than the mediastinal blood pool, this was considered as probably malignant. Substantially greater uptake was considered as definitely malignant. Indeterminate readings were rare (1%). This study suggests that greater FDG uptake is more strongly associated with malignancy. Clinically, the implication is that physicians should not only consider whether a PET scan is positive, but also consider the degree of FDG uptake when estimating the posterior probability of disease after PET imaging.[76]

PET appears to be less sensitive for lesions less than 8 mm in size, so its use should be limited to those lesions ≥8 mm in size.[2,77] While there is limited preliminary evidence that PET may be useful for lesions less than 8 mm in size, there are still too many false negatives reported to make PET useful for smaller lesions outside of a clinical trial at the current time.[78–80] False-negative findings have also been seen in patients with minimally invasive adenocarcinoma, adenocarcinoma in situ, mucinous adenocarcinomas, and carcinoids.[80,81] In one study, 18% of PET-negative solid pulmonary nodules were ultimately found to be malignant at an average of 37.6 months following detection.[82] On the other hand, false-positive results have been seen in patients with granulomatous infections, such as tuberculosis, atypical mycobacterial disease, and endemic mycoses, as well as in patients with inflammatory conditions, such as rheumatoid arthritis and sarcoidosis.[83,84] Because false-negative results can also be caused by uncontrolled hyperglycemia, blood glucose levels should be <200 mg/dL immediately prior to performing the PET scan.[85]

DISTINGUISHING BETWEEN BENIGN AND MALIGNANT NODULES

Important elements in the diagnostic approach in distinguishing benign from malignant nodules are considered below.

Estimating Probability of Malignancy

Epidemiology, knowledge of the different causes of malignant and benign nodules, and the imaging characteristics of the nodule all serve to inform the physician as to the probability of malignancy in a given nodule. While physicians often estimate pretest probability of cancer intuitively, several investigators have attempted to develop mathematical models to estimate the probability of malignancy of indeterminate pulmonary nodules.[86–89] Using clinical and radiographic characteristics of malignancy derived from the literature, these authors have analyzed some combination of the following risk factors by Bayesian, neural network, and other methods to obtain a mathematical estimate of the probability of malignancy: nodule size, location, growth rate, margin characteristics, older age, smoking history, prevalence of malignancy in the community, prior history of malignancy, interstitial lung disease, emphysema, and occult calcification on CT densitometry.[86–88,90–94] Calculators for pretest probability of malignancy have been designed where patient-specific risk factors are incorporated and a numeric probability of malignancy is obtained. The commonly used calculators are the Brock model, the VA model, and the Mayo clinic model. These calculators can help to quantify the probability of malignancy. However, these models may overestimate or underestimate the risk of malignancy when applied to other populations.[95] Other studies have shown that calculator predictions may be similar to expert clinical judgement.[96,97] These models inform and supplement decision-making but are not a substitute for clinical judgement.[96]

Assessment of the pretest probability of malignancy is central to optimal strategy selection when managing pulmonary nodules.[1,2,37,57,98] While these formulas and neural networks may lack precision on an individual patient level, they can serve to inform decision making as to what risk factors to pay attention to and how important they are relative to each other.[5] Risk factors associated with a low probability of malignancy include diameter less than 1.5 cm, age less than 45 years, absence of tobacco use, having quit for 7 or more years, and a smooth appearance on radiographic imaging. Risk factors associated with a moderately increased risk of malignancy include diameter 1.5 to 2.2 cm, age 45 to 59, smoking up to 20 cigarettes per day or being a former smoker within the last 7 years, and a scalloped edge appearance on radiography. Risk factors associated with a high risk of malignancy include a diameter of 2.3 cm or greater, age greater than 60 years, being a current smoker of more than 20 cigarettes per day, a history of prior cancer, and a corona radiata or spiculated appearance on radiography.[4,5,90,99–101]

After consideration of these risk factors and, possibly, use of one of the validated models to arrive at an estimate of the pretest probability of malignancy, physicians must then choose between alternative strategies. The main alternatives are (1) careful observation with serial CT imaging, (2) diagnostic testing with molecular assays or CT-guided biopsy or bronchoscopy, or (3) surgery. The results of each strategy help to further refine the probability of malignancy, either up or down. As such, it is important to consider the strengths and weaknesses of each of these approaches.

Careful Observation with Serial CT Imaging

Careful observation with serial CT is predicated on the ability of the imaging technology to detect nodule growth. The fundamental assumption is that by comparing serial images over time a nodule's growth rate can be determined, and this in turn can be used to help distinguish between benign and malignant nodules. Squamous and large-cell tumors have an average doubling time (i.e., the time for a nodule to double in volume) of 60 to 80 days. Adenocarcinomas double at about 120 days, and the rare small-cell carcinoma that presents as a solitary pulmonary nodule can have a doubling time of less than 30 days.[27] A nodule that has doubled in weeks to months is probably malignant and should be removed when possible.[5] Benign nodules have doubling times of less than 20 days or more than 400 days. A nodule that doubles in size in less than 20 days is usually the result of an acute infectious or inflammatory process, while those that grow very slowly are usually chronic granulomatous reactions or hamartomas. Nodules with doubling times of more than 400 days can be observed with serial radiographs.[1,2,5] This is the basis for the clinical axiom that 2-year radiographic stability is strong presumptive evidence that a solid nodule is benign.

It should be noted that controversy remains regarding how long follow-up should be continued. While traditional teaching has recommended observing lesions for a maximum of 2 years, it is now recognized that for some lesions longer follow-up may be warranted. Long doubling times have been observed in malignant lesions that presented as ground-glass nodules or as partially solid nodules.[50,55,59] Due to the concern for adenocarcinoma in situ in subsolid nodules, the recommendation is for them to be followed for up to 5 years with CT imaging.[102] The NELSON trial showed that the likelihood of malignancy in subsolid nodules is 6%; in all instances, they were stage 1 adenocarcinomas in situ.[103] However, for most solid nodules, 2 years of follow-up without evidence of growth is sufficiently long to warrant discontinuation of CT imaging.

Determination of nodule growth is based on the assumption that nodules are more or less spherical. Growth of a sphere must be considered in three-dimensional volume, not in two-dimensional diameter. The formula for volume of a sphere is $4/3(\pi)r^3$, or $1/6(\pi)d^3$, where $r =$ radius and $d =$ diameter. A nodule originally 1 cm in diameter whose diameter is now 1.3 cm has actually more than doubled in volume. Similarly, a 2-cm nodule has doubled in volume by the time its diameter reaches 2.5 cm. A nodule that has doubled in diameter has undergone an eightfold increase in volume. When old radiographs are available, growth rate and nodule doubling time can be estimated. If the diameter of a nodule is measured at two different points in time (first t1 and later at t2), then doubling time in days $= (t \times \log 2)/[3 \times \log (d2/d1)]$. In this formula, t is the number of days between t2 and t1; d1 and d2 are the diameters of the nodule at times t1 and t2, respectively. It is therefore critical that old radiographs and CT scans be obtained for comparison when evaluating pulmonary nodules, since they can provide valuable insights into the doubling time and natural history of the nodule.

Accepting the assumption that a tumor arises from serial doublings of a single cancerous cell, we can estimate that it will take 27 doublings for it to reach 0.5 cm. By the time a nodule is 1 cm in diameter, it represents 30 doubling times and about 1 billion tumor cells. Depending on the exact growth rate, this theoretical 1-cm nodule has probably existed for years before it is detected, as malignant bronchogenic tumors have doubling times estimated at between 20 and 400 days. The natural history of a tumor usually spans about 40 doublings, whereupon the tumor is 10 cm in diameter and the patient has usually died.[104]

Nodule growth rate and doubling times become clinically relevant when deciding how often to order follow-up imaging when observing a pulmonary nodule. The question often arises whether observing a pulmonary nodule for an extra 3 to 6 months increases the likelihood of metastatic disease, since that nodule has probably been growing for years. There is no convincing empiric evidence to support this hypothesis. Whether delays longer than 3 to 6 months are safe is unknown. However, estimating this risk is clinically relevant, since the optimal frequency of serial CT follow-up imaging to monitor nodules for growth is predicated on limiting this hazard of delay while containing costs and avoiding excessive radiation exposure.

The ability to detect nodule growth is a function of image resolution. CT imaging greatly improved the ability to detect nodule growth compared with conventional chest radiographs. This has made the careful observation strategy with serial imaging more effective, since it limits the hazard of delay by allowing earlier detection of growth. However, the accuracy of size measurements is still a problem when nodules are small. There is poor inter- and intraobserver variability when size differences of <1.5 mm are being assessed with two-dimensional (2D) CT.[105,106] As a result, 2D measurements of small nodules may not always be reliable. The presence of growth was incorrectly assessed in 27% to 37% of CT scan pairs when diameters or cross-sectional areas were used as compared to a reference standard of volumetric measurement.[2,107–109] Limited data suggest that volumetric measurements may provide a better alternative. When evaluated retrospectively, volumetric measurements using two CT scans performed a median of 3.7 months apart with a threshold volume doubling time >500 days were found to be 91% sensitive and 90% specific for malignancy. Another small study of predominantly solid nodules found that volumetric imaging changed management strategy in 10% of cases.[110] Volumetric imaging and doubling times were also used successfully to guide management in the NELSON lung cancer screening trial.[8] Unfortunately, volumetric measurement is time consuming and labor intensive and therefore has not yet become the standard of care.

Given this framework, it is reasonable to apply more recent expert consensus-based guidelines to help guide the frequency of follow-up CT imaging for the pulmonary nodule.[2,111,112] For follow-up studies, imaging should be performed without contrast with thin sections using low-dose techniques.[2] Where available, volumetric CT may further facilitate growth detection and limit the hazard of delay. In all cases patients should be informed about the potential benefits and harms including the hazard of delay versus the risks of unnecessary testing.

TABLE 110-3 Schedule for Conducting Serial CT Imaging on Non-Solid Nodules

	Nodules <6 mm (<100 mm^3)	Nodules >6 mm (>100 mm^3)
Single ground glass	No routine follow-up	CT 6–12 months, repeat every 2 years until 5 years have passed
Single partly solid	No routine follow-up	CT 3–6 months, then annual CT till year 5 if lesion unchanged
Multiple	CT 3–6 months, repeat at 2 years and 4 years if stable	CT 3–6 months, then management for most suspicious nodule

Data from MacMahon H, Naidich DP, Goo JM, et al. Guidelines for Management of Incidental Pulmonary Nodules Detected on CT Images: From the Fleischner Society 2017. Radiology. 2017;284(1):228–243.

Decisions about the frequency and duration of follow-up for patients with pulmonary nodules need to consider multiple dimensions of the problem, including clinical risk factors, nodule size, radiation dose, surgical risks, patient preferences, cost, and the limits of imaging technology resolution (especially at sizes less than 5 mm).[107,113,114] All of these can affect the optimal frequency of CT follow-up. The Fleischner society provides guidelines to standardize the management of these nodules. These guidelines were updated in 2017 and give recommendations on solid or subsolid pulmonary nodules found on CT chests with thin cuts (<1.5 mm). Solid pulmonary nodules are labelled as high-risk or low-risk and then divided into <6 mm, 6 to 8 mm, or >8 mm (Table 110-2), and the subsolid nodules are divided as <6 mm or >6 mm (Table 110-3). The main purposes of these guidelines are to standardize follow-up of pulmonary nodules and to decrease unnecessary CT imaging and use of resources.[102] The Fleischner guidelines do not include patients who are immunocompromised, who have known malignancies, or who are undergoing lung cancer screening.

The Lung CT Screening Reporting and Data System (LUNG-RADS) recommended by the American College of Radiology is the tool used to standardize imaging follow-up and management for pulmonary nodules in patients who undergo lung cancer screening. The classification assigns the nodule a category from 1 to 4 based on probability of malignancy, with category 1 being benign and category 4 being suspicious for malignancy. For lung cancer screening, a low-dose CT chest scan is indicated for screening of lung cancer for patients who are between ages 55 and 80, have a >30-pack-year smoking history, and are current smokers or quit <15 years ago. For patients identified with a solitary pulmonary nodule from a screening

TABLE 110-2 Schedule for Conducting Serial CT Imaging on Solid Nodules

	Nodules <6 mm (<100 mm^3)	Nodules 6–8 mm (100–250 mm^3)	Nodules >8 mm (>250 mm^3)
Single low risk	No routine follow-up	CT 6–12 months then repeat 18–24 months	CT at 3 months or PET/CT or tissue sampling
Single high risk	Optional CT at 12 months	CT 6–12 months then repeat 18–24 months	CT at 3 months or PET/CT or tissue sampling
Multiple low risk	No routine follow-up	CT 3–6 months then repeat 18–24 months	CT 3–6 months then repeat 18–24 months
Multiple high risk	Optional CT at 12 months	CT 3–6 months then repeat 18–24 months	CT 3–6 months then repeat 18–24 months

Data from MacMahon H, Naidich DP, Goo JM, et al. Guidelines for Management of Incidental Pulmonary Nodules Detected on CT Images: From the Fleischner Society 2017. Radiology. 2017;284(1):228–243.

low-dose CT, the chance of that nodule being malignant varies from 3.7% to 5.5%.[115] In the National Lung Cancer Screening trial, 24.2% of patients who underwent low-dose screening CT had a nodule, of which 11% underwent further invasive testing. Therefore, it is important that we screen, risk-stratify, and intervene on the appropriate patient population to reduce patient harm and improve outcomes (Table 110-4).

In patients with a solid indeterminate nodule or a part-solid, part ground-glass nodule that shows evidence of growth on serial imaging, a nonsurgical biopsy or surgical resection should be considered. Similarly, any patient with a pure ground-glass nodule that grows or develops a solid component should have a nonsurgical biopsy or surgical resection. If a nonsurgical biopsy is chosen, then either a specific benign diagnosis (e.g., hamartoma) or a diagnosis of malignancy must be made. If the biopsy is nonspecific (e.g., inflammation), then surgical resection should be considered.

■ Molecular Tests

For patients who are at low to intermediate risk (pretest probability of cancer $\leq$50%), proteomics may be used to inform the decision on whether to follow a serial CT strategy or to proceed to a nonsurgical biopsy of some type. Based on the PANOPTIC study, a venous blood sample can measure the relative abundance of two plasma proteins (LG3BP and C163A). The ratio of these proteins is determined and combined into a model with five clinical/imaging factors (age, smoking status, nodule size, edge characteristics, and location) to generate a risk classifier. In the PANOPTIC trial, patients who had a likely benign result had a 98% probability of not having cancer. In select patients with a pretest probability $\leq$50% in which this test demonstrates a likely benign etiology, serial CT imaging may be the best strategy. Conversely, an indeterminate result from the test suggests that a nonsurgical biopsy be pursued.[116] However, there has only been one study so far to validate these findings, so these results should be interpreted cautiously. Other blood biomarkers are being evaluated and may have a role to play in the management of pulmonary nodules in the future. Another tool that has been studied is a genomic classifier collected from a bronchial brush of a normal-appearing mainstem bronchus to assess the probability of lung cancer. In patients with intermediate pretest probability of lung cancer and a nondiagnostic bronchoscopy, a negative genomic classifier result may help in pursuing a strategy of repeat imaging compared with a nonsurgical biopsy. The weakness of this strategy is that it requires a bronchoscopy to be done, as opposed to other molecular diagnostics that can be done using a blood test. Currently, this test is not widely used in practice.

■ Nonsurgical Biopsy Techniques: CT-Guided Transthoracic Needle Biopsy

CT-guided transthoracic needle biopsy is most useful for peripheral lesions in the outer third of the lung. The sensitivity of CT-guided transthoracic needle biopsy for malignancy is 90%.[117] The major limitation of CT-guided transthoracic needle biopsy is its high rate of pneumothorax, with reported rates ranging from 10% to 35% overall.[42,118] In a recent cross-sectional analysis of 15,865 patients, the rate of any pneumothorax was 15% and the rate of pneumothorax requiring a chest tube was 7%.[119] Risk factors associated with pneumothorax include older age, smoking, emphysema, smaller lesions, deeper locations, lateral puncture site, proximity to fissures, and low entry angle to the pleura.[1,120,121] Because of the high rate of pneumothorax and its possible complications, the following patients should not undergo percutaneous needle aspiration: those with severely limited pulmonary reserve, those with bullous emphysema or blebs in the needle path, and postpneumonectomy patients. Other relative contraindications are bleeding diathesis, inability to hold breath, and severe pulmonary hypertension.

TABLE 110-4 Lung CT Screening Reporting and Data System (LUNG-RADS) for Screen-detected Nodules

LUNG-RADS Score	Findings	Management	Risk of Malignancy
0—Incomplete	Incompletely imaged lung fields or prior CT being located	Obtain additional images or compare with prior CT	—
1—Negative	• No lung nodules • Nodule with complete, central, popcorn, or concentric calcification	Annual LDCT in 12 months	<1%
2—Benign Appearance	• Perifissural nodule <10 mm • Solid nodule <6 mm • Part-solid nodule <6 mm Ground glass nodule <30 mm or >30 mm unchanged	Annual LDCT in 12 months	<1%
3—Probably Benign	• Solid nodule ≥6 to <8 mm • Part-solid nodule ≥6 mm with solid part <6 mm • Ground glass nodule ≥30 mm	LDCT in 6 months	1%–2%
4A—Suspicious	• Solid nodule ≥8 to <15 mm *or* growth <8 mm Part-solid nodules ≥6 mm with solid part ≥6 mm to <8 mm • Endobronchial nodule	LDCT in 3 months or PET/CT if solid component >8 mm	5%–15%
4B—Suspicious	• Solid nodule ≥15 mm *or* growth ≥8 mm • Part-solid nodule with solid part ≥8 mm *or* growth ≥4 mm	Chest CT, PET/CT, or tissue sampling	>15%
4X—Suspicious	Category 3 or 4 nodules with additional features that increase suspicion for malignancy	Chest CT, PET/CT, or tissue sampling	>15%

Data from Lung-RADS® Version 1.1. American College of Radiology. 2019.

Importantly, CT-guided transthoracic needle biopsy does not always provide a specific benign or malignant diagnosis. Such nondiagnostic results occur in 4% to 41% of cases.[2] Because of this, if the pretest probability of cancer is high, then a nondiagnostic result does not necessarily rule out malignancy and additional testing or observation with serial CT may be warranted.

■ Nonsurgical Biopsy Techniques: Bronchoscopy

Traditionally, conventional bronchoscopy has been regarded as a procedure of limited usefulness in the evaluation of pulmonary nodules.[122,123] Studies have shown variable success rates, with an overall diagnostic yield of 36% to 68% in nodules greater than 2 cm with bronchoscopic biopsy, brushings, and washings.[124,125] In general, the yield for specific benign diagnoses has ranged from 12% to 41%.[32,124] Complication rates are low at about 1% to 2%, with most of the risk being associated with the transbronchial biopsy component of the bronchoscopy.[126,127]

Factors to consider when deciding on the suitability of bronchoscopy for diagnosis of a pulmonary nodule include the size of the nodule, its location, the presence of air bronchograms, and the availability of new bronchoscopic technologies. In terms of nodule size, the sensitivity of conventional bronchoscopy is significantly worse for smaller lesions. The overall sensitivity when performing bronchoscopy with cytology brushing, bronchoalveolar lavage, and transbronchial biopsy under fluoroscopic guidance was 34% for lesions <2 cm and 63% for lesions >2 cm.[117,126,128,129] Location also matters: nodules located in the inner or middle one-third of the lung have the best diagnostic yield, whereas nodules in the outer one-third have a much lower diagnostic yield and as such are often best approached with CT-guided transthoracic needle aspiration. Another characteristic of pulmonary nodules to consider is the relation of the nodule to neighboring bronchi.[117] Tsuboi et al. described four types of tumor–bronchus relationships: (1) the bronchial lumen is patent up to the tumor; (2) the bronchus is contained in the tumor mass; (3) the bronchus is compressed and narrowed by the tumor, but the bronchial mucosa is intact; and (4) the proximal bronchial tree is narrowed by peribronchial or submucosal spread of the tumor or by enlarged lymph nodes[130] (Fig. 110-5). The presence of types 1 or 2, a bronchus leading to or contained within the body of a nodule or mass on CT, has been termed a positive bronchus sign. When a bronchus sign is present on CT, the diagnostic yield of bronchoscopy can be as high as 60% to 90%.[20,117,131,132] With a negative bronchus sign, the yield drops to 14% to 30%. Signs and symptoms of airway involvement (cough, hemoptysis, localized wheezing), although rare in pulmonary nodules, will increase diagnostic yield when present.

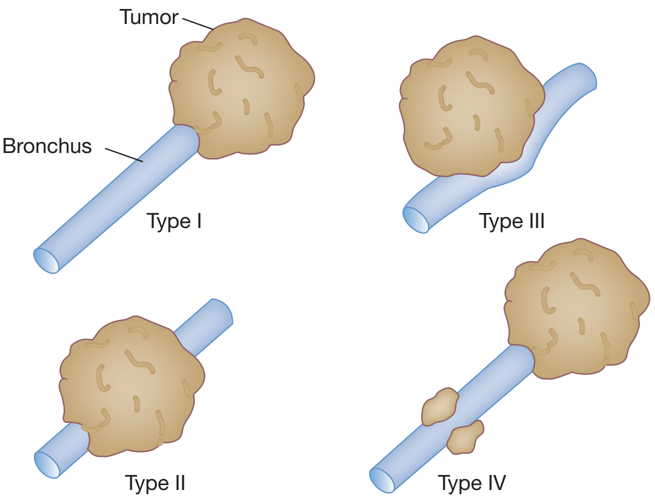

Figure 110-5 Schematic illustration of tumor–bronchus relationships (see text). *(Data from Tsuboi E, Ikeda S, Tajima M, et al. Transbronchial biopsy smear for diagnosis of peripheral pulmonary carcinomas. Cancer. 1967;20(5):687–698.)*

Newer bronchoscopic technologies include electromagnetic navigation and guidance (EMN), radial endobronchial ultrasound (r-EBUS), ultrathin bronchoscopy, guide sheath techniques, and virtual bronchoscopic navigation (Chapters 33 and 34). EMN uses navigation software that provides bronchoscopic guidance to reach the target peripheral nodule. Once the bronchoscope is within vicinity of the nodule, a transbronchial forceps biopsy, transbronchial needle aspiration, or cytologic brushings can be performed. R-EBUS uses real-time ultrasound to provide a 360-degree image of the airways. Once an abnormal lesion is identified with the radial probe, biopsies of the lesion can be performed with or without the guide-sheath. R-EBUS and EMN can also be used together.

In meta-analyses of EMN, the pooled sensitivity for malignancy was found to be 70.7% to 77%.[126,133–135] Meta-analyses of r-EBUS with transbronchial biopsy demonstrated an overall diagnostic sensitivity of 70.6% to 72%.[133,136,137] Note that in many of the studies cited, investigators would use multiple modalities concurrently—for example, a study using r-EBUS with a guide sheath and virtual bronchoscopy would be included in all three categories. As such, it is difficult to tell the contribution of individual system components, since what is truly relevant is overall aggregate system performance. In addition, many of the studies did not report on the method of patient selection, but it is clear that proper patient selection is vital if high diagnostic yields are to be obtained with these technologies, since they are not suitable for all patients. The meta-analyses also found significant heterogeneity between studies, and therefore sensitivity may vary significantly across institutions. The main risk with EMN and r-EBUS is pneumothorax; however, that risk is only around 0.7% to 2%.[136,137] Studies have found that size greater than 2 cm, presence of an air bronchus sign on CT scan, and use of rapid on-site cytologic evaluation are associated with an increase in the diagnostic yield of r-EBUS and EMN.[136–138] It does appear that the time required to reach the lesion is less when using both modalities together compared to when either is used alone.[139]

Emerging modalities such as robotic bronchoscopy and cone-beam CT-guided bronchoscopy are being investigated for sampling of peripheral lung nodules. Preliminary data suggest that they are feasible and their safety data are encouraging, but their diagnostic sensitivity is not yet well measured.[140–143] Further studies of these modalities are needed before they can become standard of care.

On balance, EMN, EBUS, and VB appear to increase the diagnostic sensitivity of bronchoscopy in select centers with the appropriate expertise, although the magnitude of the benefit for each of these technologies is difficult to quantify and there is a paucity of randomized controlled data. In cases in which there is an air-bronchus sign or very central lesions abutting the large airways, bronchoscopy may be of use. Similarly, if there is a suspicion for an infectious etiology (e.g., tuberculosis or fungal infections), then bronchoscopy may be warranted.

■ Surgery: Thoracotomy and Thoracoscopy

Surgical biopsy can be achieved with video-assisted thoracoscopic surgery (VATS), traditional thoracotomy, or a combination of both. If the frozen section demonstrates a benign lesion, then only a wedge resection may be required—and if that is the case, then operative mortality will be low (~0.5%).[57] Conversely, if the lesion is malignant and the patient has sufficient pulmonary reserve a lobectomy using either open thoracotomy or VATS with systematic lymph node sampling remains the standard of care.

Lobectomy mortality is 1% to 4%.[1] Mortality is higher in patients over age 70 and in patients with malignancy. These patients will often have other coexisting illness, such as chronic obstructive pulmonary disease (COPD) or coronary artery disease. The mortality risk increases with the extent of the procedure. In one series, the mortality was 1.4% for wedge resection, 2.9% for lobectomy, and 6.2% for pneumonectomy.[144] A more recent observational study of lung cancer surgery reported similar 30-day mortality rates.[145] Of note, this study indicated that there may be a relationship between volume of surgeries performed and outcome. Hospitals that performed the highest volume of lung cancer surgeries had lower 30-day mortality than those that had the lowest volume (3% vs. 6%).

VATS uses fiberoptic telescopes and miniaturized video cameras to facilitate biopsies and resection. VATS represents a complementary approach to traditional thoracotomy and can be very useful in some patients. This approach still requires general anesthesia but does not require a full thoracotomy incision or spreading of the ribs. VATS allows the experienced surgeon to identify and wedge out peripheral nodules in many cases with minimal morbidity and mortality. In a series by Mack et al., 242 nodules were resected with no mortality and minimal morbidity.[146] Average hospital stay was 2.4 days. VATS can spare some patients with benign nodules the risks of open thoracotomy and can be useful for wedging out nodules in patients who have limited pulmonary reserve who cannot otherwise tolerate a lobectomy. However, in up to 12% of cases conversion from VATS to a minithoracotomy will still be required.[147–151]

Whether resection is performed by VATS or by thoracotomy, lobectomy with systematic lymph node sampling remains the procedure of choice for malignant solitary pulmonary nodules.[152] Wedge excisions or segmental resections for smaller cancers have been evaluated, but the role of these limited pulmonary resections in the management of lung cancer remains controversial. The Lung Cancer Study Group evaluated this in a study of 276 patients with T1N0 lesions that were strictly staged to prove N0 status. Patients were randomized to lobectomy or limited resection.[153] In patients undergoing limited resection, there was an observed 75% increase in recurrence rates ($p = 0.02$) attributable to an observed tripling of the local recurrence rate ($p = 0.008$), an observed 30% increase in overall death rate ($p = 0.08$), and an observed 50% increase in death with cancer rate ($p = 0.09$) compared to patients undergoing lobectomy. Because of the higher death rate and locoregional recurrence rate associated with limited resection, lobectomy stands as the surgical procedure of choice for patients with peripheral T1N0 non–small-cell lung cancer.

For patients with insufficient pulmonary reserve to tolerate a lobectomy, segmentectomy or wedge resection remains a viable alternative. In addition, whether very small malignant lesions, less than 2 cm in size, can be managed with segmentectomy, radiation, or some combination thereof, remains controversial and is the subject of ongoing research. The original randomized trial used both wedge resections and segmentectomy, but more recent data suggest that segmentectomy is superior to wedge resection for tumors less than 2 cm in size.[154–156] At the present time, it is reasonable to recommend lobectomy with systematic lymph node dissection for all patients with malignant solitary pulmonary nodules who have sufficient pulmonary reserve to tolerate the procedure, with consideration of segmentectomy for those patients with inadequate pulmonary function to tolerate a lobectomy.

THE IMPACT OF SURGICAL RISK ASSESSMENT ON DIAGNOSTIC STRATEGY

For patients with pulmonary nodules, the probability of malignancy should be assessed. If the probability is close to 0, then a strategy of careful observation with CT is recommended. If the probability of malignancy is close to 1, then directly proceeding to surgery after staging work-up will be the best strategy. For patients with an intermediate probability for malignancy, a nonsurgical biopsy should be pursued. The probability at which the strategy changes from observation to nonsurgical biopsy is the "observation threshold," and the probability at which the strategy changes from nonsurgical biopsy to surgical resection is the "surgical threshold" (Fig. 110-7, Table 110-5). These decision thresholds are determined by the sensitivity and specificity of the available tests as well as the treatment threshold. The treatment threshold is the probability of disease at which the expected outcome of treatment and no treatment are exactly the same (Table 110-5).

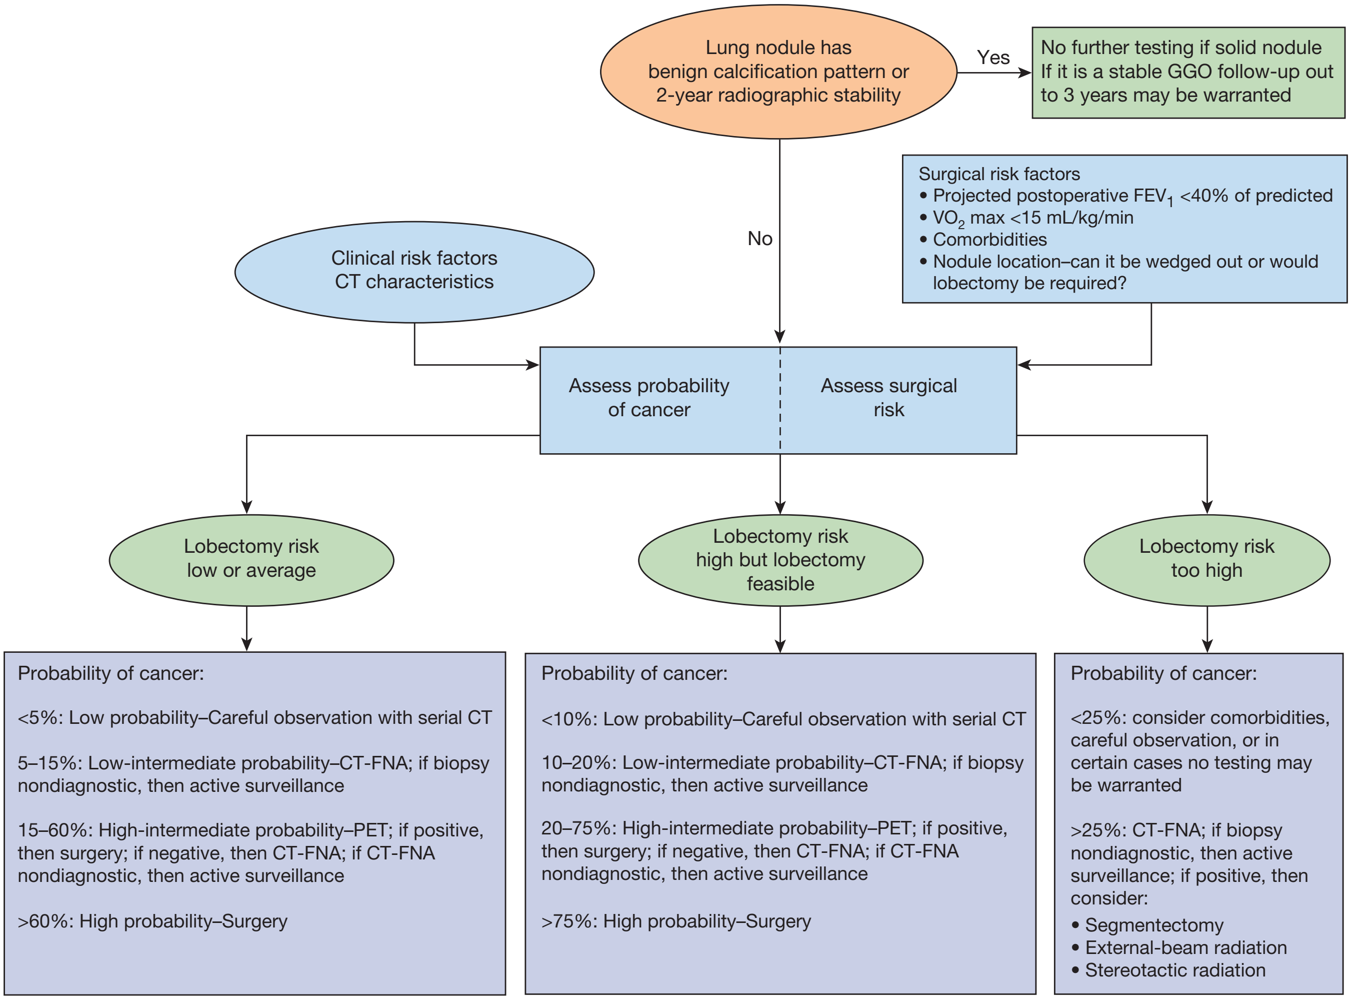
Algorithms for pulmonary nodules assign a probability of 5% to the "observation threshold" and a probability of 60% for the "surgical threshold."[1,2] However, these numbers vary significantly from patient to patient based on their surgical risks, comorbidities, and personal preferences (Fig. 110-6). The surgical threshold will be higher for patients with a higher surgical risk and multiple comorbidities compared to a patient with the same pulmonary nodule without those risk factors. It is also important to recognize that the decision thresholds of 5% and 60% are based on the assumption that a surgical wedge resection for the pulmonary nodule is possible. A wedge resection serves to limit the harm of surgery in benign nodules, since morbidity and mortality are much lower than with a lobectomy. If a wedge resection of a nodule is not possible because of nodule location such that a lobectomy is required for access, then the harms increase and thus treatment and decision thresholds increase.[1,157] Other factors, such as competing risks from comorbidities and patient preferences, will also change the decision thresholds as shown in Fig. 110-7.

SYSTEMATIC APPROACH TO THE PULMONARY NODULE

The goal is to promptly identify and bring to surgery all patients with operable malignant nodules while avoiding thoracotomy in patients with benign nodules. Based on the previous discussion, the systematic approach to the pulmonary nodule should begin with a history and physical. The history and physical should focus on addressing the following questions: (1) What is the pretest probability of cancer? (2) What is the patient's surgical risk? This should include a detailed history of relevant comorbidities that impact surgical risk as well as severe competing diseases (e.g., severe Alzheimer disease) that significantly limit life expectancy independent of cancer and surgical risk.

Surgical risk assessment should include spirometry and diffusion capacity for carbon monoxide (DL_{CO}). If pulmonary function is not normal, then quantitative perfusion scans may be warranted to calculate the projected postoperative FEV_1 and DL_{CO}. If the projected postoperative FEV_1 and DL_{CO} are at least 40% of predicted, the risk of pulmonary complications following surgery is acceptable. If one of the two measures is less than 40% while the other is at least 40%, pulmonary exercise testing may be useful to further risk-stratify the patient. A $\dot{V}O_{2max} \geq 15$ mL/kg/min is associated with a low risk of pulmonary complications following lobectomy. Other factors to consider include the location of the nodule. If the nodule is very peripheral and easily reached by VATS and wedge resection is feasible, then the potential harm of resecting a benign lesion will be relatively low. Conversely, if the nodule is very central, such that the only way to obtain a surgical biopsy is to do a lobectomy, then the potential harm of resecting a benign lesion will be high. These considerations in turn will impact the treatment threshold and hence optimal strategy.

A chest CT should be ordered if not already available and compared with all old chest radiographs and CT images (if available). A pretest probability of cancer should be estimated, based on clinical and radiographic features. If the lesion is a solid nodule and has demonstrated radiographic stability for 2 or more years, no additional evaluation is warranted—but a period of 5 years of stability is necessary for pure ground-glass nodules to be deemed to be benign.



Lung nodule has
benign calcification pattern or
2-year radiographic stability
Yes
No further testing if solid nodule
If it is a stable GGO follow-up out
to 3 years may be warranted
No
Surgical risk factors
• Projected postoperative FEV$_1$ <40% of predicted
• VO$_2$ max <15 mL/kg/min
• Comorbidities
• Nodule location–can it be wedged out or would lobectomy be required?
Clinical risk factors
CT characteristics
Assess probability of cancer
Assess surgical risk
Lobectomy risk low or average
Lobectomy risk high but lobectomy feasible
Lobectomy risk too high
Probability of cancer:
<5%: Low probability–Careful observation with serial CT
5–15%: Low-intermediate probability–CT-FNA; if biopsy nondiagnostic, then active surveillance
15–60%: High-intermediate probability–PET; if positive, then surgery; if negative, then CT-FNA; if CT-FNA nondiagnostic, then active surveillance
>60%: High probability–Surgery
Probability of cancer:
<10%: Low probability–Careful observation with serial CT
10–20%: Low-intermediate probability–CT-FNA; if biopsy nondiagnostic, then active surveillance
20–75%: High-intermediate probability–PET; if positive, then surgery; if negative, then CT-FNA; if CT-FNA nondiagnostic, then active surveillance
>75%: High probability–Surgery
Probability of cancer:
<25%: consider comorbidities, careful observation, or in certain cases no testing may be warranted
>25%: CT-FNA; if biopsy nondiagnostic, then active surveillance; if positive, then consider:
• Segmentectomy
• External-beam radiation
• Stereotactic radiation

TABLE 110-5 Definitions and Formulas for Decision Analysis of Solitary Pulmonary Nodules

Harm	Difference in outcome between similar patients *without* the disease who do not receive treatment and those who receive treatment
Benefit	Difference in outcome between similar patients *with* the disease who receive treatment and those who do not receive treatment
Treatment threshold	*Harm/(harm* + *benefit)* = 1/(1 + [*benefit/harm*])
Observation threshold	*(Harm x false — positive ratio)/(harm x false — positive ratio)* + (*benefit x true — positive ratio*) Probability at which the strategy changes from observation to nonsurgical biopsy
Surgical threshold	(*Harm x true — negative ratio)/(harm x true — negative ratio*) + (*benefit x true — false negative ratio*) Probability at which the strategy changes from nonsurgical biopsy to surgical resection

True-positive ratio, sensitivity; false-positive ratio, (1 – specificity); true-negative ratio, specificity; false-negative ratio, (1 – sensitivity).

At this point the physician should integrate the probability of cancer with the relative consequences of treatment. Treatment consequences should be considered by comparing the benefits of surgery if the patient has cancer with the potential harm of surgery if the patient does not have cancer. This determines the treatment threshold, which is the point around which the decision centers. These thresholds vary significantly between patients depending on their cardiopulmonary reserve, comorbidities, and individual preferences. Patient preferences for certain outcomes can play an important role in strategy selection, so physicians should discuss the risks and benefits of alternative strategies and elicit patient preferences.[2,37,91,158] Management strategies can then be selected based upon the patient's surgical risk, probability of disease, and patient preferences (Fig. 110-7).

There have been many decision analysis studies of solitary pulmonary nodules published over time, and the probability of cancer that defines low-, intermediate-, and high-probability risk groups varies between studies.[37,91,159,160] In part, this is because diagnostic tests and treatments have changed over time so the underlying probability thresholds will of course vary over time. As new diagnostic and treatment alternatives become available, these thresholds need to be periodically reassessed.[161] However, even if technology were unchanging, patient characteristics and preferences vary significantly, so defining a single "optimal answer" for all patients is not feasible. Given these constraints, all of the decision analyses published are fairly consistent, with low probability being approximately 5% to 12% or less, and high probability being approximately 60% to 72%.[57,91,159,160] When the

Treatment Threshold

Figure 110-7 Decision and treatment thresholds for diagnostic strategy of pulmonary nodules. The observation and surgical thresholds vary depending on individual patient comorbidities, surgical risk factors, patient preferences, and the availability of diagnostic tests and treatments. For example, increased comorbidities and surgical risk increase the surgical threshold. Improved detection of nodule growth with volumetric CT increases the observation threshold. *(Reproduced with permission from Ost DE, Gould MK. Decision making in patients with pulmonary nodules. Am J Respir Crit Care Med. 2012;185(4):363–372.)*

pretest probability is low, a PET scan will not be as useful because the specificity of PET is only 83%.[20,57] A positive PET scan increases the posttest probability of cancer, but the posttest probability of cancer will not be above the surgical threshold so it is not high enough to make a definitive treatment decision. We can use the same approach to understand why PET is preferred when the pretest probability is in the high-intermediate range. Imagine that the pretest probability is just below the surgical threshold. The pretest probability is so high that any single negative test will not result in a posttest probability below the observation threshold. Thus, a second negative test would be needed to lower the probability below the observation threshold. However, PET carries much less risk to the patient than CT-FNA. If PET is performed first when the pretest probability of cancer is high, the posttest probability will be high enough to warrant surgery and the risks of CT-FNA will be avoided.

Keeping this in mind, we can gain some useful insights of a more general nature from a careful examination of Fig. 110-7. While decision thresholds for individual patients vary because of the surgical risk, and hence the potential benefit and harm of surgery vary, the order of the preferred strategies is the same when going from lowest to highest pretest probability of cancer: careful observation with serial CT, then CT-FNA or peripheral bronchoscopy, then PET with possible CT-FNA or peripheral bronchoscopy, and then surgery. The decision between pursuing bronchoscopy compared to CT-FNA is based on location, size, availability of equipment, and expertise. CT-FNA is the most sensitive test for obtaining a definitive diagnosis; however, it has a pneumothorax complication rate of approximately 20%. The sensitivity of bronchoscopy improves as size increases, and since the complication rate of bronchoscopy is lower, bronchoscopic options are more competitive for larger lesions and select lesions with an air bronchus sign.

For most patients with peripheral pulmonary nodules without mediastinal adenopathy on PET-CT who are surgical candidates, conventional bronchoscopy will not play a major role since the sensitivity of CT-guided biopsy is considerably higher. However, in patients with emphysema or concerns of not tolerating CT-guided biopsy, peripheral bronchoscopy techniques such as EMN, r-EBUS, and robotic bronchoscopy can be considered since they are safer than CT-guided biopsy with the caveat of a lower sensitivity. In patients with a radiographically negative mediastinum and a pulmonary nodule in the inner one-third of the lung, c-EBUS of the mediastinum should be performed. This should be followed by peripheral bronchoscopy if the mediastinum is negative for malignancy on rapid on-site cytology examination. For patients with a peripheral pulmonary nodule less than 3 cm located in the outer two-thirds of the lung, performance of bronchoscopy for the additional purpose of staging the mediastinum is not essential if the patient is being considered for resection.[122,123] However, for patients being considered for stereotactic body radiation therapy, mediastinal staging with c-EBUS with concurrent peripheral bronchoscopic biopsy if needed should be performed, since stereotactic body radiation is contingent on not having any nodal disease (including N1).

SUMMARY

Evaluation of pulmonary nodules should begin with estimating the pretest probability of cancer. For patients with a very low probability of cancer, careful observation with serial CT is warranted. For those with a very high probability of cancer, surgery is preferred. For patients with an intermediate probability of cancer, either CT-FNA or peripheral bronchoscopy is best. Patient preferences should be considered because individual patients vary significantly in terms of their risks, potential for benefit, and preferences.

CHAPTER 111

The Pathology of Bronchogenic Carcinoma

Leslie A. Litzky

INTRODUCTION

The development of new classes of drugs and targeted therapy for lung cancer prompted an extensive reevaluation of the pathologic classification of bronchogenic carcinoma but did not diminish the significance and impact of the histologic classification of bronchogenic carcinoma. Rather than marginalizing the traditional role of the pathologist in lung cancer treatment, the advent of what has been termed “personalized” or “precision” medicine has only made pathologic assessment more crucial to patient management.[1,2] The clinical necessity of providing rapid and concurrent molecular/immunologic analysis along with a histologic diagnosis has placed the anatomic pathologist in the additional central strategic management role of tumor tissue processing and evaluation, in addition to frequent consultation on optimal sample acquisition. This chapter focuses on the major histologic subtypes of malignant pulmonary epithelial tumors and includes carcinoid tumors, sarcomatoid carcinoma, and salivary gland tumors. Other unusual tumors, both benign and malignant, are covered in a separate chapter, and there is another chapter on the genetic and molecular changes in lung cancer. The extremely rapid pace of developments in molecular diagnostics and therapy makes it quite difficult to make enduring summary statements about the prognostic and therapeutic implications for specific histologic subtypes. New molecular and immunologic insights are leading to entirely new classes of drugs that are continuously impacting, and in some cases dramatically improving, overall survival statistics. The intent of this chapter, therefore, is to provide a broad overview of the current histologic classification and to provide a deeper understanding of the critical issues regarding the preanalytic steps of sampling, processing, and evaluating lung cancer specimens for molecular analysis.

GENERAL CONSIDERATIONS IN HISTOLOGIC CLASSIFICATION AND THE CURRENT CLASSIFICATION OF LUNG TUMORS

Pathologic assessments are continually refined to reflect changes in surgical and medical management, as well as to incorporate an improved understanding of basic tumor biology. Once the diagnosis of malignancy had been made, the pathologic evaluation of lung cancer had traditionally focused on histologic subtyping and, for the selected subset of patients undergoing surgical resection, determining the pathologic stage of disease. Histologic classification is essentially predicated on the assumption that the quantitative predominance of a particular histologic pattern reflects distinctive biologic characteristics. It has been gratifying to note that concurrent developments in other disciplines such as molecular biology have substantiated many aspects of the currently accepted framework for histologic classification. The 2004 World Health Organization (WHO) classification of lung tumors was the first edition to extensively summarize the molecular biology of different tumor subtypes.[3] Nevertheless, the main purpose of the 2004 WHO classification was to provide reproducible criteria to pathologists worldwide by using recognizable architectural patterns and individual cellular features that can be appreciated by routine light microscopy and standard hematoxylin- and eosin-stained slides. The use of ancillary techniques, such as immunohistochemistry or molecular biology, was not required in most instances, thereby making the classification accessible to all pathologists for diagnosis and fostering consistency in treatment and research protocols. Although this approach might seem antiquated, it should be noted that the incorporation of data from ancillary studies such as immunohistochemistry or molecular analysis has broad implications, not the least of which is the expense of the laboratory tests, which require additional time, special equipment, technical expertise, and the possibility of exhaustion of small tumor samples that are then no longer available for future testing. By the time of the 2015 WHO classification, the requirement for immunohistochemistry in the accurate diagnosis and subclassification of many lung tumors was clearly inescapable.[4] The WHO classification was traditionally based on a detailed histologic examination of resection specimens, despite the unfortunate fact that the majority of lung cancer patients present with advanced disease and never undergo resection. Personalized treatment, especially in patients with advanced lung cancer who often have limited samples, required histologic classification to be as precise as possible. The most recent 2021 WHO classification directly addresses in detail the issue of pathologic classification of small biopsy samples and cytopathology specimens.[5]

Tumor classification and associated generalizations pertaining to tumor type are often made to seem relatively straightforward but, in practice, it is always a challenge for any proposed scheme of histopathologic classification to ensure the reproducible recognition of tumor subtypes. The degree to which histologic heterogeneity is recognized and tumors classified depends to some extent on sampling techniques, and that may, in turn, have implications for protocol design and data evaluation. The effects of prior therapy must also be considered in subsequent biopsies. It is a fundamental fact of lung tumor classification that small samples taken from advanced-disease patients may not be entirely representative of the tumor—either in terms of histology or in molecular alterations. The histologic subtyping of pulmonary carcinomas on the basis of morphology alone is even more challenging in small samples. With the advent of targeted therapies for non–small-cell carcinoma, further pathologic subclassification beyond the traditional distinction between small-cell carcinoma and non–small-cell carcinoma is now considered critical for selecting appropriate treatment for patients.[1] Subsequent sections will address the expanded use of immunohistochemical stains for further histologic subclassification as well as the competing priority of preserving sufficient tumor for molecular analysis.

Lung carcinomas are classified according to the best differentiated component, and pathologists assign a degree of differentiation to tumors that show differentiation, such as squamous cell carcinoma and adenocarcinoma. This is also known as histologic grading, and it is used in tumor pathology as a way of attributing prognostic significance to a specific histologic pattern. It is an assessment as to how much the tumor cells phenotypically resemble a normal cell type, such as a squamous cell or a glandular cell. Histologic grading should not be viewed as a histogenetic determination, that is, that a tumor is derived from a specific cell of origin, such as a squamous cell, or that the tumor cell has “dedifferentiated” from a cell of origin. Traditionally, there have been three histologic degrees of differentiation: well differentiated, moderately differentiated, and poorly differentiated. Many lung tumors show a wide variation in differentiation. If a tumor is largely undifferentiated but contains recognizable foci of squamous cell carcinoma or adenocarcinoma, it is classified as a poorly differentiated squamous cell carcinoma or adenocarcinoma, respectively. Some tumors, such as small-cell carcinoma or sarcomatoid carcinoma are, by definition, poorly differentiated. In recent years, the most intense focus has been on developing an improved and more standardized histologic grading system that is more prognostically robust, particularly for pulmonary adenocarcinomas, and these efforts will be summarized in the subsequent section on adenocarcinoma.

INVASIVE ADENOCARCINOMA, INCLUDING ADENOCARCINOMA IN SITU AND MINIMALLY INVASIVE ADENOCARCINOMA

Adenocarcinoma is the most common histologic subtype in the United States and in most countries.[6] Adenocarcinoma is also the most frequently diagnosed subtype in nonsmokers.[7] The classification of pulmonary adenocarcinoma has long been a source of controversy—not only because of its diversity in histologic appearance but also because of a wide spectrum of clinical behavior, radiographic findings, and molecular characteristics associated with the entity. It is worth reviewing a concise history of the revisions in lung adenocarcinoma classification to understand the conceptual framework of the current 2021 WHO classification. The inherent histologic heterogeneity of many primary pulmonary adenocarcinomas has always made reproducible subclassification difficult, and even small adenocarcinomas (<2 cm) can contain more than one histologic pattern.[8] This practical problem was addressed by the 1999 WHO revision, which introduced for the first time a *mixed* subtype to the four previously recognized subtypes of *acinar*, *papillary*, *bronchioloalveolar*, and *solid*.[9] In addition, a strict definition for bronchioloalveolar carcinoma (BAC) was adopted in the 1999 revision and retained in the 2004 classification. The definition required that the tumor have a pure lepidic growth pattern without evidence of stromal, vascular, or pleural invasion.[3,9] The term *lepidic* means that the proliferation of tumor cells should line the alveolar walls in a uniform manner, using the alveolar walls as a supporting scaffold. It should be noted that prior to the 1999 revision, pathologists widely varied in their assessments. Adenocarcinomas with a minor, usually central, and often more poorly differentiated invasive glandular component along with a peripheral bronchioloalveolar pattern are frequently encountered. In instances in which the peripheral BAC component predominated, it had been a common practice to designate the tumor either as a BAC or an "adenocarcinoma with a BAC pattern/features." The stricter definition of BAC prevailed in the revisions because of evidence demonstrating that small (<2 cm) solitary tumors with a pure lepidic growth pattern had a 100% 5-year survival.[10] Histologically, BACs were divided into two major subtypes, *nonmucinous* and *mucinous*, and were grouped together because of a similar "lepidic" growth pattern along alveolar septa. The more common nonmucinous type consists of cuboidal, columnar, or so-called hobnail cells with apical nuclei. The mucinous type consists of tall columnar cells with abundant apical pale mucinous cytoplasm and basally located nuclei, sometimes resembling goblet cells. A rare *mixed nonmucinous and mucinous* or *indeterminate* subtype was also recognized in the 1999/2004 revisions.

While this classification of BAC made sense from a histologic pattern perspective, it did not really encompass the variability in clinical presentation, radiographic features, or prognosis. Although practice patterns changed somewhat after these revisions, the diagnosis of BAC continued to be used for both small and well-differentiated adenocarcinomas as well as for more advanced-stage tumors with obvious diffuse pneumonic spread or lymph node involvement. Moreover, in the years following the publication of the 2004 WHO classification, it became increasingly apparent that the nonmucinous and mucinous cell types have distinctive clinical, radiographic, immunophenotypic, and molecular correlations.[11,12] In 1995, Noguchi et al. had suggested that even small foci of invasion in what would otherwise be a pure BAC were associated with a 100% disease-free survival, and following the publication of the 2004 WHO classification, there were a number of other studies that similarly supported quantitation of the lepidic growth pattern and the area of invasion within these "mixed" type adenocarcinomas. These studies focused on a cutoff of 5 mm or less of invasion as a way of defining a "minimally invasive adenocarcinoma" (MIA) with an excellent survival.[13,14]

The 2015 WHO classification completely discarded the term *BAC* in favor of *adenocarcinoma in situ* (AIS). For small (≤3 cm) solitary adenocarcinomas with predominant lepidic growth and small foci of invasion measuring ≤0.5 cm, the term *minimally invasive adenocarcinoma* was recommended.[4] By definition, MIA can be applied only to a solitary and discrete lesion unless it is clear, in the instance of multiple tumors, that they are synchronous primaries. Although the new terminology was a bit unsettling to pathologists and clinicians who have long been used to the entity of BAC, the terms *AIS* and *MIA* were favored because they more accurately reflect both the histologic growth pattern and survival statistics. AIS and MIA will typically present as pure ground-glass opacities without a solid component or with a very small solid component on computed tomography (CT) scans.[15] The majority of AIS and MIA cases are nonmucinous, although some cases of mixed nonmucinous and mucinous MIA have been reported (Fig. 111-1).[16] Most lesions with a mucinous "BAC" histologic pattern, if carefully examined and sampled, will have invasive foci and, therefore, are classified as "invasive mucinous adenocarcinoma" (Fig. 111-2A,B).

The 2021 WHO classification recommends that invasive nonmucinous adenocarcinomas be characterized by a predominant subtype and recognizes five major patterns: lepidic predominant, acinar predominant, papillary predominant, micropapillary predominant, and solid predominant.[5] The introduction of a "predominant" pattern was intended as a practical way to evaluate the characteristic heterogeneity of many adenocarcinomas and to allow for better stratification than the previous "mixed subtype." The recommendation was based on studies in stage I tumors that suggested that these different histologic patterns had prognostic value in a grading system and that these different patterns can be reproducibly recognized.[16–18] Other studies have further validated the prognostic significance of the predominant histologic pattern using this classification system or have evaluated other potential parameters for

a grading system.[19–22] The 2021 WHO classification further recommends that any pattern present in a resected specimen be estimated in a semiquantitative fashion and recorded in 5% to 10% increments totaling 100% pattern (although this has been variably adopted in past and current practice). The practice of estimating percentages for each component has been incorporated into a new proposed grading scheme for pulmonary adenocarcinoma that redefines the traditional well, moderate, and poorly differentiated criteria with a significantly improved predictive model for early-stage resected adenocarcinomas (see subsequent discussion).[23] *Lepidic predominant adenocarcinoma* consists mainly of tumor cells growing along alveolar septae (previously referred to as a nonmucinous BAC pattern) but with greater than 5 mm invasion. *Acinar predominant adenocarcinoma* consists of irregularly contoured but nonetheless recognizable glandular structures and is often associated with a desmoplastic stroma (Fig. 111-3A). Within the acinar group, there is a subgroup of complex glandular patterns that are considered to be high-grade. These include *cribriform* (defined as nests of tumor cells with sieve-like perforations) and fused gland (defined as poorly formed fused glands without intervening stroma or in a ribbon-like formation with irregular borders and single cells infiltrating a desmoplastic stroma).[5] *Papillary predominant adenocarcinoma* consists of malignant cuboidal or columnar cells that line the surface of fibrovascular cores (Fig. 111-3B). *Micropapillary predominant adenocarcinoma* consists of small papillary clusters of glandular cells growing within airspaces (Fig. 111-3C).[5] To this classic description of micropapillary adenocarcinoma has been added a newly recognized *filigree* pattern. The filigree pattern is characterized as tumor cells growing in delicate, lace-like, narrow stacks of cells without fibrovascular cores.[24] *Solid predominant adenocarcinoma* consists of sheets of tumor cells without an acinar, papillary, micropapillary, or lepidic growth pattern (Fig. 111-3D). The tumor cells have abundant cytoplasmic and mostly vesicular nuclei with prominent nucleoli. Multiple tumor cells have basophilic cytoplasmic vacuoles that suggest intracytoplasmic mucin, which then may be confirmed by a special stain for mucin. The 2015 WHO classification required that be there five or more mucin-positive cells in at least two high-power fields (0.4 mm^2) for the diagnosis of *solid adenocarcinoma.* This criterion was adopted because it is not uncommon for squamous cell or large cell carcinomas to have rare mucin droplets. However, the use of TTF-1 immunohistochemistry is more sensitive than mucin and is preferentially used wherever immunohistochemical stains are easily available. Supporting evidence for glandular differentiation also can be provided by a positive napsin A stain and/or a negative p40 stain.

The general acknowledgment that there should be a more comprehensive grading system for pulmonary adenocarcinomas led to efforts to define a supplemental grading system within the parameters of the current classification. One recent study based on carefully staged resection specimens matched with clinical outcome data suggested a combination of the predominant plus high-grade histologic pattern (with a cutoff of 20% for the high-grade pattern) that was both practical and prognostic for invasive pulmonary adenocarcinomas.[23] In this model, lepidic predominant is grade 1. Grade 2 consists of acinar or papillary predominant tumors with no or less than 20% of high-grade patterns. Grade 3 is any tumor with 20% or more of high-grade patterns (solid, micropapillary, or complex gland patterns).

There are four other variants of invasive adenocarcinoma in the 2021 WHO classification: *invasive mucinous adenocarcinoma* (formerly mucinous BAC), *colloid adenocarcinoma*, *fetal adenocarcinoma*, and *enteric adenocarcinoma*.[5] The historically recognized variants of *signet-ring adenocarcinoma* and *clear cell adenocarcinoma* were discarded as discrete entities and are now viewed as cytologic changes that can occur in association with multiple histologic patterns and are therefore not included in the comprehensive histologic description, although it is useful to document these patterns for comparison of histologic features with tumor recurrence or metastasis.[5]

Invasive mucinous adenocarcinoma is a primary pulmonary adenocarcinoma with tumor cells that show goblet cell or columnar cell morphology with abundant intracytoplasmic mucin.[5] There is also a less common variant of *mixed invasive mucinous and nonmucinous adenocarcinoma*. There is no established grading system for invasive mucinous adenocarcinoma, and it is often the case that the tumor cells are deceptively bland in appearance. Although much of the tumor can appear noninvasive and grow in a lepidic manner, careful sectioning usually reveals invasive foci that can appear as acinar, papillary, micropapillary, or solid patterns. Invasive mucinous adenocarcinomas are peripheral tumors and frequently present as multifocal, multilobar, and/or bilateral tumors, that may reflect aerogenous spread. This tumor often grows in a pneumonic-like pattern, producing consolidation that is initially misinterpreted as infection. Radiographic presentation as a part-solid or solid nodule also occurs, and particularly with multilobar and bilateral involvement, the question of an extrapulmonary primary is often raised. Without careful clinical and radiographic correlation, it can be exceedingly difficult to distinguish a pulmonary primary from other extrapulmonary primary sites including the pancreaticobiliary system, gastrointestinal tract, and ovary on a morphologic and even immunohistochemical basis.

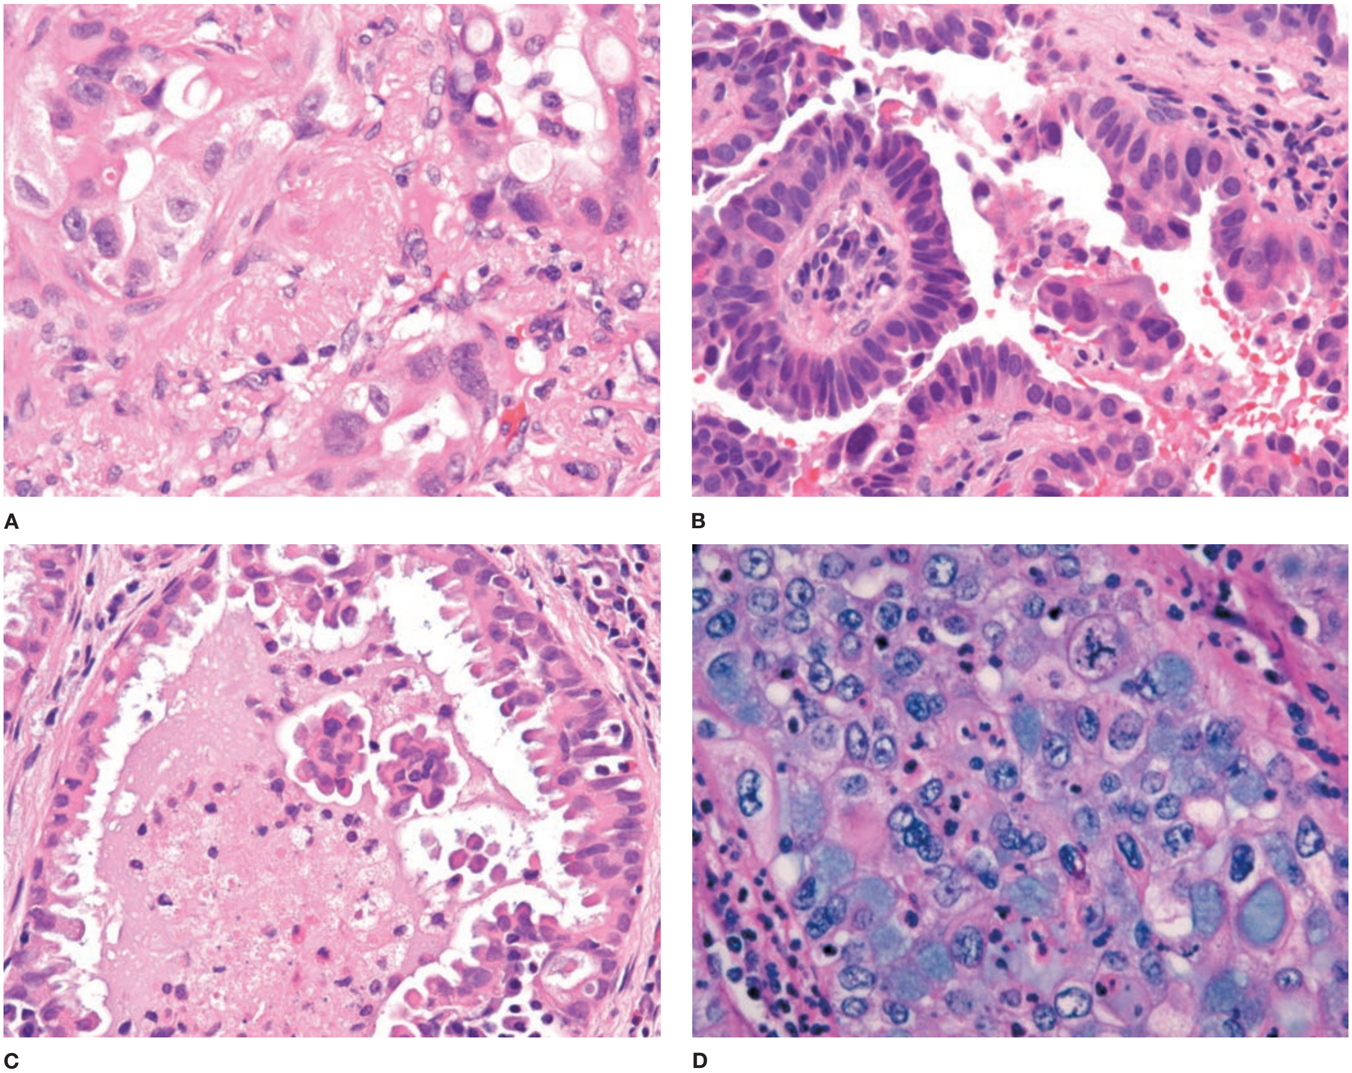

Figure 111-3 **A.** Invasive pulmonary adenocarcinoma, acinar predominant. Small, irregularly shaped glands within a desmoplastic stroma (H&E, 400×). **B.** Invasive pulmonary adenocarcinoma, papillary predominant. Malignant cells are arranged on the surface of fibrovascular cores (H&E, 400×). **C.** Invasive pulmonary adenocarcinoma, micropapillary predominant. Small papillary clusters without fibrovascular cores (H&E, 400×). **D.** Invasive pulmonary adenocarcinoma, solid predominant. Solid nests of cells with mucin (H&E, 400×).

Enteric adenocarcinoma is an important variant because of its morphologic and immunohistochemical overlap with colorectal adenocarcinomas, thereby necessitating a clinical evaluation to exclude a gastrointestinal primary.[5] The need to exclude a metastatic mucinous adenocarcinoma from other primary sites such as the GI tract, pancreas, and breast is a similar concern when diagnosing a primary pulmonary *colloid adenocarcinoma. Fetal adenocarcinoma* is a rare entity that resembles the developing fetal lung in its pseudoglandular stage. There are both low-grade and high-grade variants.

The reproducibility of histopathologic subtype and invasion in pulmonary adenocarcinomas has been studied.[25] In pulmonary adenocarcinomas with classic morphology, there is good reproducibility in identifying a predominant pattern but only fair reproducibility in distinguishing invasion from in situ (purely lepidic) patterns. Specifically recognizing stromal invasion is still somewhat problematic in practice, even among expert thoracic pathologists. Many adenocarcinomas have areas of fibrosis due to alveolar wall collapse or septal fibrosis, with some observers interpreting an individual case as tumor-related stroma with fibroblasts (desmoplastic stroma) and others interpreting as benign fibroelastotic scarring. Histologic criteria for true invasion include single cell infiltration, a fibromyxoid stromal response, high-grade cytology, and a cribriform or acinar growth pattern.

Most adenocarcinomas arise in the periphery of the lung and are often associated with parenchymal scarring or puckering of the overlying pleura (Fig. 111-4). It is now a standard recommendation for accurate staging to use elastin stains in the evaluation of visceral pleura invasion in any lesion that approaches the visceral pleura (Fig. 111-5).[26,27] Histologic subtype alone cannot be used to replace molecular analysis in predicting which lung cancers have mutations and are likely to respond to targeted therapy. The current recommendation is to submit a sample for molecular testing whenever the sample is sufficient.[28]

The histologic heterogeneity of adenocarcinomas is such that the exclusion of metastatic disease or malignant mesothelioma is often an important consideration. As mentioned previously in the enteric variant of adenocarcinoma, the exclusion of a colorectal primary (among others) may be important. Other features such as signet-ring cytology raise the possibility of a gastric or appendiceal tumor as well as other primary sites. Mucinous carcinomas, particularly of pancreatic or ovarian origin, may metastasize to the lung and mimic a mucinous adenocarcinoma. All the classic growth patterns—acinar, papillary, micropapillary, or solid—may be seen in any number

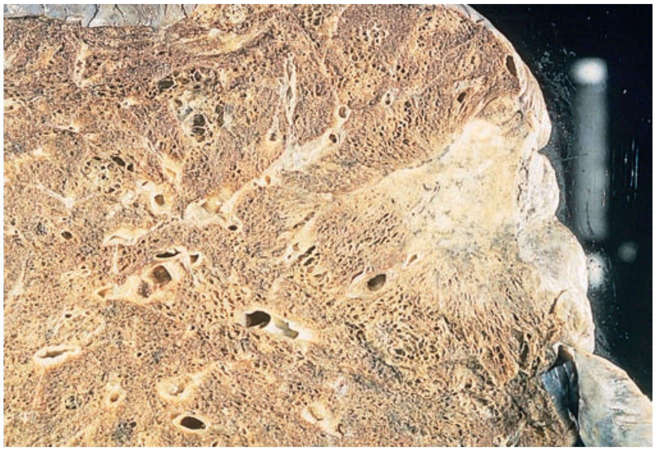

Figure 111-4 Peripheral adenocarcinoma of the lung with pleural puckering.

of extrapulmonary primaries, and clinicoradiologic correlation is always essential. The distinction between peripheral adenocarcinomas with extensive pleural involvement, diffuse carcinomatous involvement of the pleura by metastatic tumor, and malignant mesothelioma may be similarly problematic. Some carcinomas grow in a manner virtually identical to malignant mesothelioma, with extensive pleural involvement and limited parenchymal invasion.[29] Clinically, radiographically, and macroscopically, these tumors are indistinguishable from malignant pleural mesothelioma. The histologic appearance may be equally confusing, requiring the use of immunohistochemical stains. As will be discussed further in the general section on immunohistochemistry, there are multiple antibodies that will stain adenocarcinomas of the lung. Many of these antibodies (CEA, MOC31, B72.3, LeuM1, and BerEP4) recognize glycoproteins and are not specific for the lung. Surfactant protein A (SP-A), TTF-1, and Napsin A are the three commercially available markers that can be useful in the diagnosis of lung adenocarcinomas, with the latter two markers having higher sensitivity for lung adenocarcinomas.[30,31] It is important to recognize that neither TTF-1 nor Napsin A are entirely specific for lung adenocarcinomas and pathologists must still consider within the differential diagnosis a number of extrapulmonary tumors, depending on the clinical circumstances. The combined use of TFF-1 and Napsin A does result in improved sensitivity and specificity for identifying primary pulmonary adenocarcinomas.[32]

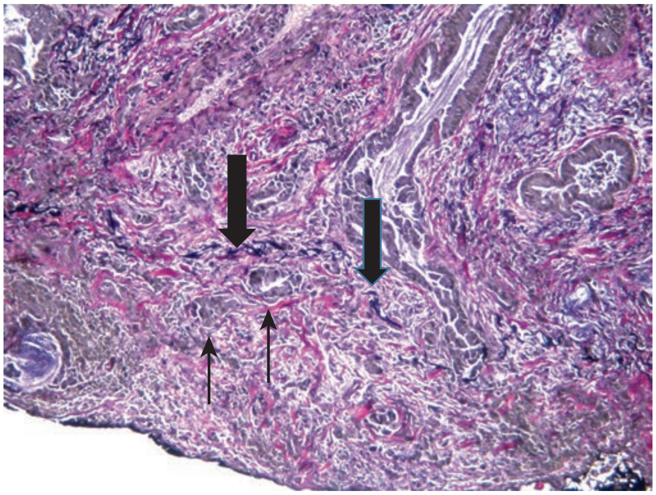

Figure 111-5 Visceral pleural invasion. Tumor cells *(thin black arrow)* are present beyond the black elastic layer of the visceral pleura *(thick black arrow)*. (Elastin, 100×).

SQUAMOUS CELL CARCINOMA

Despite its replacement as the leading lung cancer cell type among both men and women in the United States and in many other countries, squamous cell carcinoma remains an important histologic subtype. Squamous cell carcinoma is still very strongly correlated with cigarette smoking. About two-thirds of squamous cell carcinomas occur centrally, where involvement of a mainstem, lobar, or segmental bronchus may be demonstrated, but squamous cell carcinoma may also present as a peripheral mass and the incidence of this appears to be increasing—especially in patients with underlying interstitial lung disease[33] (Fig. 111-6A,C). As would be expected from an endobronchial growth pattern, squamous cell carcinomas often are associated with bronchial obstruction and postobstructive pneumonia. Cavitation with superimposed infection can be seen in peripheral tumors[5] (Fig. 111-6B).

In the 2021 WHO classification, squamous cell carcinoma is defined as a malignant epithelial tumor characterized by the presence of keratinization, intercellular bridges, or immunohistochemical markers of squamous differentiation (with p40 being the most recommended and specific immunohistochemical stain).[5] This latter criterion represents a significant departure from the traditional reliance on morphologic characteristics alone to classify these tumors. There are two major entities in the 2021 WHO classification of squamous cell carcinoma: squamous cell carcinoma and lymphoepithelial carcinoma (see separate section). Within squamous cell carcinoma, there are three subtypes: keratinizing, nonkeratinizing, and basaloid. On occasion, a tumor may consist entirely of one of these subtypes, but mixed tumors with both a basaloid and keratinizing or nonkeratinizing component do occur. A familiarity with these variant patterns is useful for the practicing pathologist, but at the current time there is no evidence that these variant patterns have any clinical significance. Keratinization may be in the form of squamous pearls or individual cells with dense eosinophilic cytoplasm. Intercellular "bridges" are seen in paraffin sections due to cell shrinkage caused by fixation and correspond to the desmosomal attachments that can be appreciated ultrastructurally (Fig. 111-7B,C). A desmoplastic (i.e., fibrotic) response is often associated with the invasive nests of tumor cells (Fig. 111-7A). The nonkeratinizing variant requires the use of immunohistochemistry to separate it from large-cell carcinoma in both small biopsies and resections. In the basaloid variant, the nests of tumor cells have prominent peripheral palisading and have less cytoplasm toward the periphery, but the more centrally located cells have more obvious keratinization. The basaloid histologic features in lung carcinomas are similar to those also seen in other extrapulmonary sites such as the head and neck or cervix. Squamous cell carcinomas with a greater than 50% basaloid component should be classified as basaloid carcinoma. Basaloid cells are typically described as relatively small monomorphic cuboidal to fusiform cells with moderately hyperchromatic nuclei, finely granular chromatin, absent or focal nucleoli, scant cytoplasm, and a high mitotic rate. Intercellular bridges and/or individual cell keratinization may be seen but are often absent or inconspicuous. The tumor cells are usually arranged in lobular, trabecular, or palisading growth patterns (Fig. 111-8). Since these types of histologic patterns can also be seen in neuroendocrine tumors, immunohistochemical stains for neuroendocrine markers should be negative or extremely focal. The basaloid variant of squamous cell carcinoma, in particular, can pose a diagnostic dilemma in small, poorly preserved biopsies when the relatively scant cytoplasm mimics small-cell carcinoma. In this instance, a panel of immunohistochemical stains that includes markers of

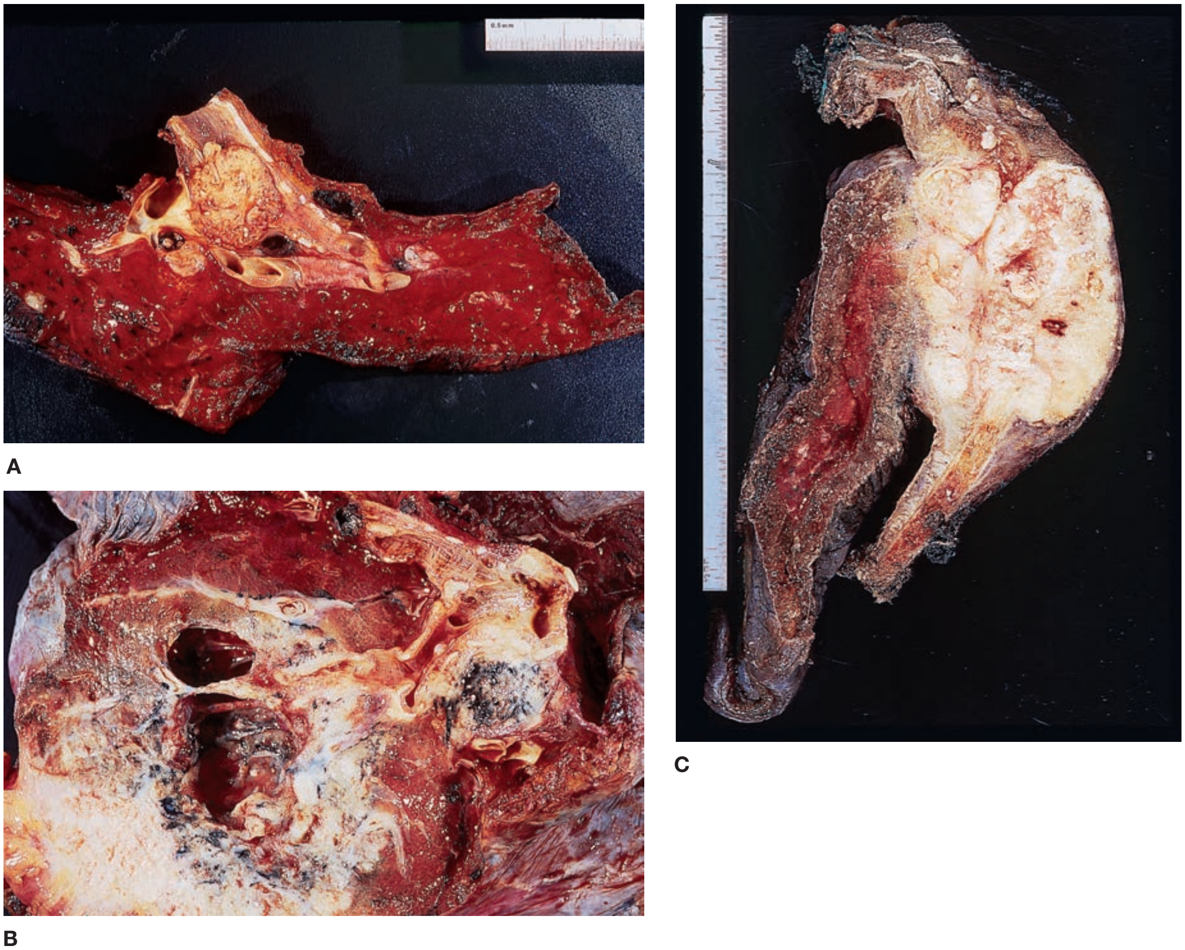

Figure 111-6 **A.** Large endobronchial squamous cell carcinoma with atelectasis and obstructive pneumonitis. **B.** Cavitation within a squamous cell carcinoma. **C.** Right upper lobectomy with chest wall resection for squamous cell carcinoma.

squamous and neuroendocrine differentiation is essential for interpretation.

Although not invariably demonstrated, it is easiest to identify a trend in tumor progression with the squamous cell histologic subtype. Sampling of a resected specimen may show changes in the adjacent bronchial mucosa ranging from squamous metaplasia to dysplasia to carcinoma in situ. If identified, the presence of an in situ component helps to differentiate a primary squamous cell carcinoma from a metastatic lesion. Aside from a clear-cut transition from in situ to invasive squamous cell carcinoma, there is no other conclusive morphologic means of differentiating a primary pulmonary squamous cell carcinoma from a metastasis. There is a tendency for metastatic tumors from the head and neck to be better differentiated (i.e., show more extensive keratinization) than their primary pulmonary counterparts, but reliably distinguishing a primary squamous cell carcinoma of the lung from other primary sites, particularly from the head and neck, continues to be an ongoing issue. Although availability may be regionally limited or not clinically indicated, multigenic panels and human papillomavirus (HPV) testing/genotyping can be helpful in defining the primary site of some cases of squamous cell carcinomas when the clinicopathologic data are equivocal and when the distinction is critical for treatment or prognosis.[5] Separation from a urothelial or thymic primary also can be problematic with immunohistochemical panels being of limited utility.

ADENOSQUAMOUS CARCINOMA

This tumor consists of squamous carcinoma and adenocarcinoma components, with each component composing at least 10% of the whole tumor.[5] The areas of glandular and squamous differentiation may be located in different areas of the tumor or may be intimately admixed. In the past, different criteria had been used for this histologic subtype, and these differences in definition, in addition to its low incidence, have made it extremely difficult to compare survival rates with other non–small-cell carcinomas. The tumor is more common in smokers but does occur in nonsmokers, and the incidence is estimated at 2% to 3%.[5] The tumor is more common in the periphery but also occurs centrally. Studies support a worse prognosis with adenosquamous carcinoma when compared to other non–small-cell carcinomas of the lung.[5] Molecular data show that the two components contain similar driver mutations, thereby suggesting a clonally identical tumor and not a "collision" tumor. Targeted therapy selection is currently based on the genetic abnormalities found in lung adenocarcinomas.

LARGE CELL CARCINOMA

The widespread use of immunohistochemistry in addition to the generation of a significant amount of genomic data has markedly reduced the incidence of large cell carcinoma from its traditional proportion of about 10% of all lung cancers to about 1.5%.[5,35] The tumor, like other non–small-cell lung cancers, is much more common in current or former smokers. Large cell carcinoma is defined in the 2021 WHO classification as "an undifferentiated non-small-cell carcinoma malignant epithelial tumor that lacks the cytologic, architectural, and immunohistochemical features of small-cell carcinoma, adenocarcinoma, or squamous cell carcinoma, in addition to giant cell, spindle cell, or pleomorphic carcinoma." The tumor cells typically have large

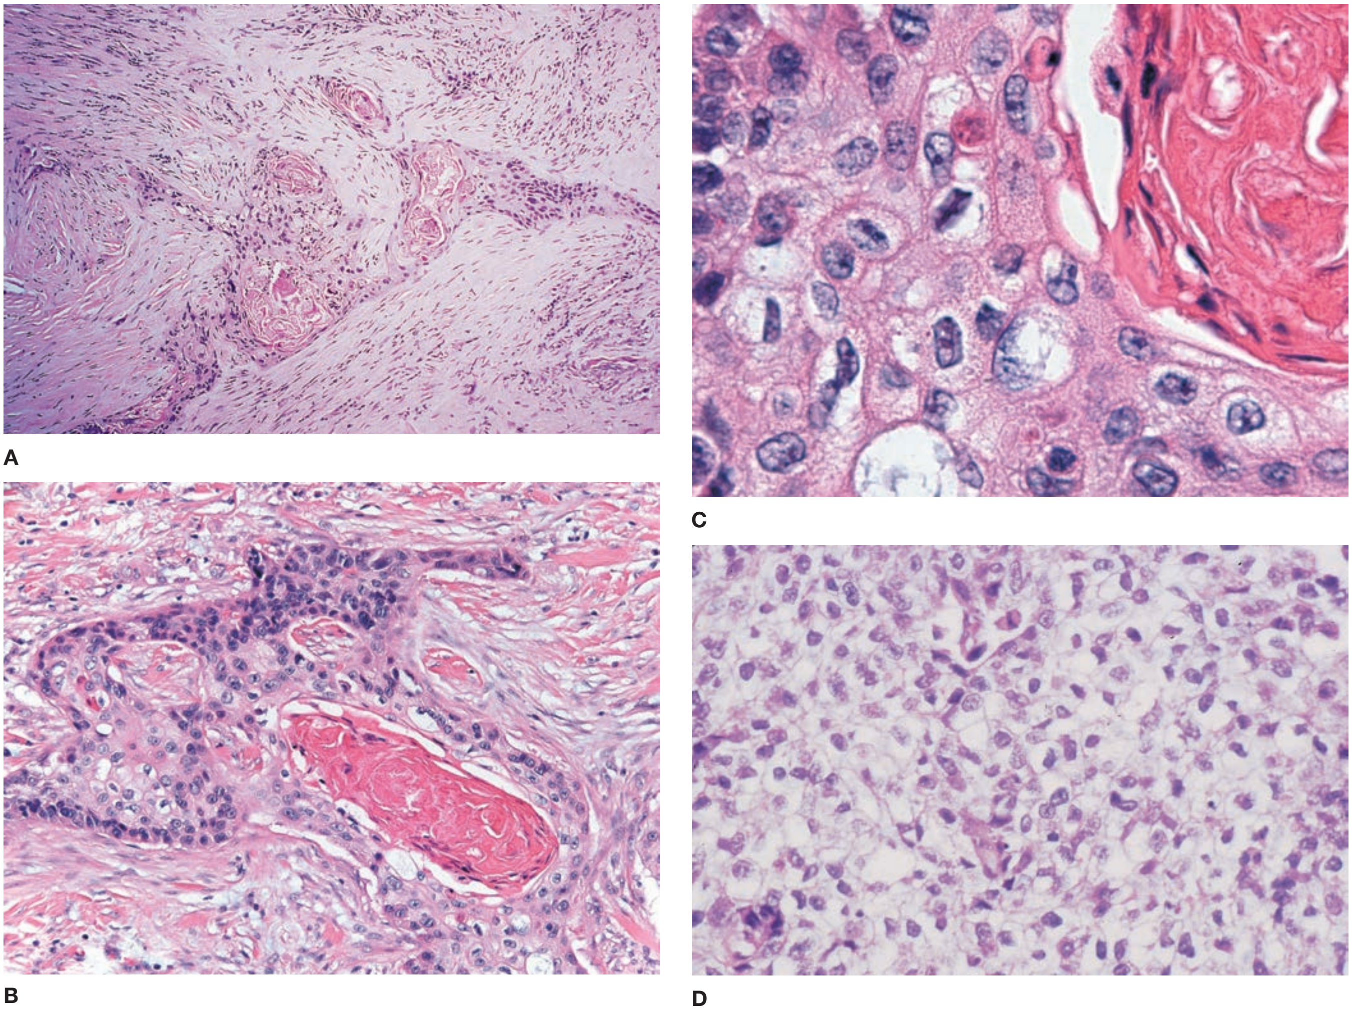

Figure 111-7 **A.** Desmoplastic response with nests of infiltrating squamous cell carcinoma (H&E, 200×). **B.** Squamous cell carcinoma with keratinization and intracellular bridges (H&E, 200×). **C.** High-power view of keratinization and intercellular bridges (H&E, 400×). **D.** Tumor cells with clear cytoplasm from a squamous cell carcinoma (H&E, 400×).

nuclei, prominent nucleoli, and a moderate amount of cytoplasm (Fig. 111-9). As is evident from this description, this tumor is defined more by what it is not than what it is. For practical purposes, it is a diagnosis of exclusion, and the diagnosis of large cell carcinoma requires morphologic examination of the resected tumor as well as immunohistochemistry. Besides other types of non–small-cell carcinoma, melanoma, malignant large cell lymphomas, and epithelioid sarcomas also can mimic large cell carcinoma, typically requiring the use of immunohistochemistry to exclude these diagnoses. Several entities that were previously included under the large cell carcinoma

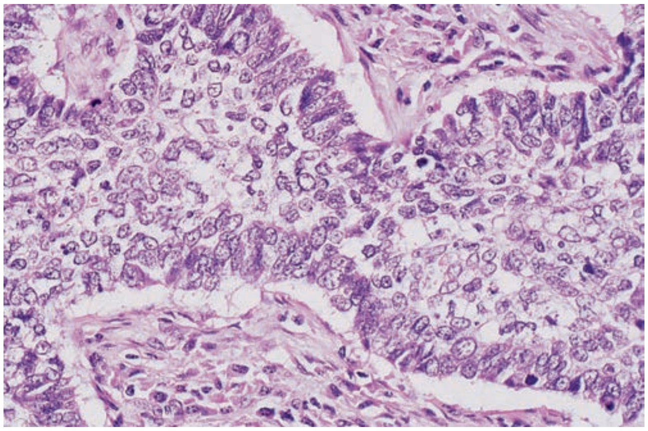

Figure 111-8 Basaloid carcinoma of the lung. The tumor cells are relatively small with hyperchromatic nuclei and scant cytoplasm. Note the tendency of the tumor cells to palisade at the periphery of the tumor nest (H&E, 400×).

category are now classified elsewhere in the 2021 WHO classification. *Large cell neuroendocrine carcinoma* is now part of the neuroendocrine tumor classification and *lymphoepithelioma-like carcinoma (now renamed lymphoepithelial carcinoma)* is classified as a separate entity under squamous cell carcinoma (see subsequent section).[5] Tumors with clear cell or and rhabdoid features are not considered variants, although these features should be noted.

It had long been known and generally acknowledged that the majority of large cell carcinomas represented either very poorly differentiated adenocarcinomas or squamous cell carcinomas. By electron microscopy, many large cell carcinomas had shown focal ultrastructural features consistent with adenocarcinoma or a poorly differentiated squamous cell carcinoma.[36] Similar subsets within large cell carcinoma can be defined using the same immunohistochemical stains that are routinely employed to distinguish between adenocarcinoma and squamous cell carcinoma, and the distribution of targetable mutations can be generally correlated with the immunophenotyping profile.[37] After having separated out poorly differentiated adenocarcinomas and squamous cell carcinomas, there still remains a small subset of tumors that are not classifiable as anything other than marker-null large cell carcinomas.[35] Multivariate analysis has demonstrated that these marker-null subsets of large cell carcinoma, though rare, are associated with clinically aggressive behavior. The current paucity of actionable molecular alterations has significant implications for predictive molecular testing strategies and individualized therapy.

■ Lymphoepithelial Carcinoma (Formerly Lymphoepithelioma-Like Carcinoma)

In the 2021 WHO classification, *lymphoepithelial carcinoma* is defined as a poorly differentiated squamous cell carcinoma admixed with variable amounts of lymphoplasmacytic infiltrate, frequently associated with Epstein-Barr Virus (EBV). Lymphoepithelial carcinomas are extremely rare (<1% of non–small-cell lung carcinomas), and predominantly affect younger, Asian, nonsmokers (median age of about 50 years).[5] This rare pulmonary tumor was first reported in the lung in 1987 and the morphologic features are identical to undifferentiated nasopharyngeal carcinoma of the head and neck.[38] Large malignant cells with prominent nucleoli are arranged in nests within a lymphoid-rich stroma (Fig. 111-10). In Asian patients, EBV is found in >90% of cases but occurs at a much lower rate in patients of European descent. Survival rates are better than in patients with conventional non–small-cell carcinomas, stage for stage.[5]

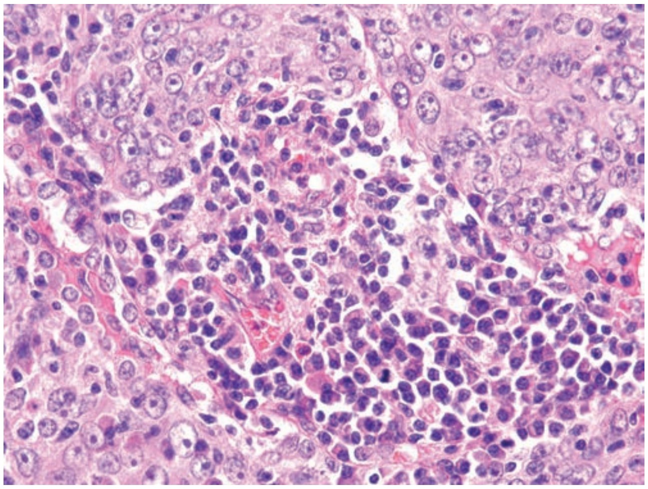

Figure 111-10 Lymphoepithelial carcinoma. Large malignant cells with prominent nucleoli are arranged in nests within a lymphoid-rich stroma (H&E, 400×).

SARCOMATOID CARCINOMA

Tumors that have sarcoma-like elements such as malignant spindle or giant cells or have a sarcomatous component that consists of a neoplastic but differentiated connective tissue phenotype such as neoplastic bone, cartilage, and striated muscle have been described in many primary organ sites, including the lung. The proliferation of terms in past literature and even the variations in nomenclature that have characterized revisions in the WHO classification has generated a disproportionate degree of confusion when compared with the actual incidence of these relatively rare lung tumors. Various terms in the literature have included spindle cell carcinoma, sarcomatoid carcinoma, carcinosarcoma, pleomorphic carcinoma, giant cell carcinoma, and pulmonary blastoma. The current 2021 WHO classification variants of sarcomatoid carcinoma include *pleomorphic carcinoma*, *carcinosarcoma*, and *pulmonary blastoma.*[5] It is now accepted that these variants are phenotypic variations that can occur within the spectrum of epithelial-derived lung tumors and the term *sarcomatoid carcinoma* can be used as an encompassing term for these tumors. Careful sampling of these tumors will often demonstrate an identifiable component of squamous cell carcinoma, adenocarcinoma, or large cell carcinoma. As with other entities in the WHO classification, the diagnosis of sarcomatoid carcinoma cannot be made on the basis of a cytology or small biopsy specimen. Features suggestive of the tumor in a small sampling may be mentioned on a descriptive basis, that is, non–small-cell carcinoma, not otherwise specified (NOS) with a comment on the sarcomatoid features.[5] Any additional identifiable component (adenocarcinoma or squamous cell carcinoma) also should be mentioned, as this might affect treatment.

Pleomorphic carcinoma is defined as a poorly differentiated non–small-cell carcinoma, including adenocarcinoma, squamous cell carcinoma, and/or large cell carcinoma containing at least a 10% component of spindle cells and/or giant cells, or a carcinoma that consists entirely of spindle and/or neoplastic giant cells[5] (Fig. 111-11). The incidence of these tumors in resected specimens is about 2% to 3%.[5] They are frequently large and peripheral, often with chest wall invasion. Most patients are former or current smokers. The giant cells in this tumor are bizarre, dyscohesive, and multinucleated. The spindle cells may be overtly cytologically malignant or may be deceptively bland. The tumor is, by definition, poorly differentiated. *MET* exon 14 skipping mutations have been identified in some tumors.[5]

Carcinosarcoma is a malignant tumor consisting of non–small-cell components combined with at least one sarcomatous heterologous

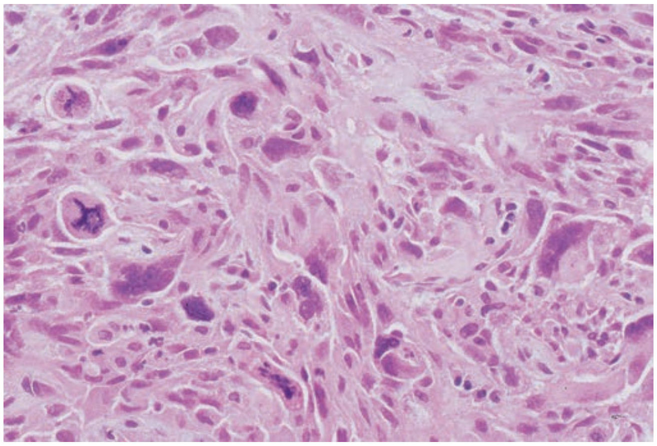

Figure 111-11 Pleomorphic carcinoma of the lung. The spindle cell and giant cell component in this large-cell carcinoma constitute at least 10% of the tumor (H&E, 400×).

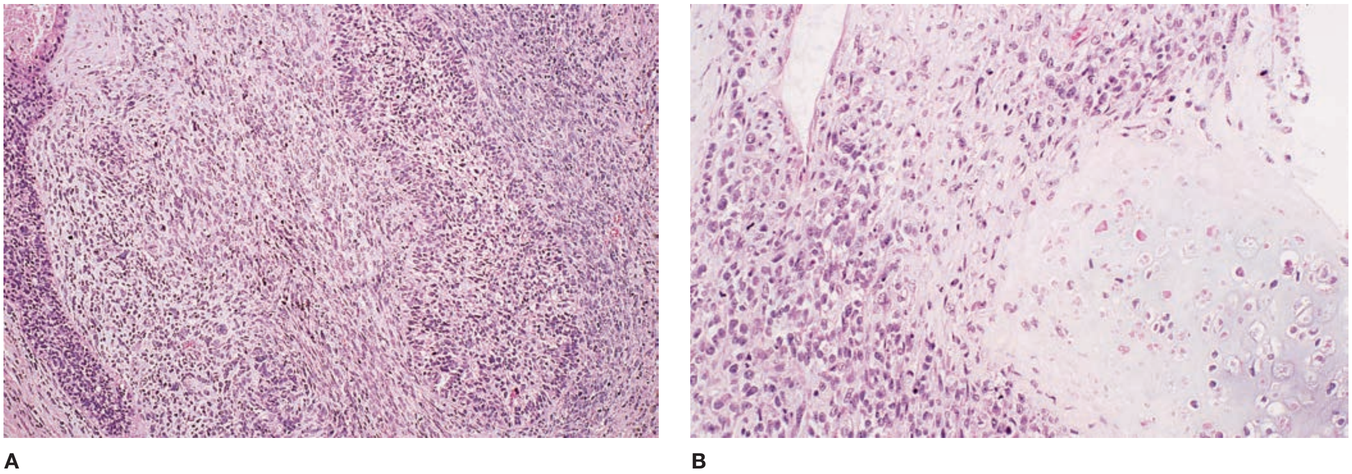

Figure 111-12 **A.** Carcinosarcoma showing a mixture of sarcoma (center) and carcinoma (periphery) (H&E stain, 100×). **B.** Tumor includes a malignant cartilaginous component (H&E stain, 100×).

element.[5] In the pathology literature, tumors that contain cells with a neoplastic but differentiated connective tissue phenotype are said to have "heterologous elements." Recognizable heterologous elements include rhabdomyosarcoma, osteosarcoma, or chondrosarcoma (Fig. 111-12). Rather than terminology, the more significant issues confronting the pathologist are exclusion of metastasis from another site and avoiding the misdiagnosis of a primary pulmonary sarcoma. The incidence of these tumors in resected specimens is <0.2%.[5] The tumor can be central, endobronchial, or peripheral. Most patients are former or current heavy smokers. Like other sarcomatoid carcinomas, these tumors have a poor prognosis.

Pulmonary blastoma is a biphasic tumor that consists of a low-grade fetal adenocarcinoma/well-differentiated fetal adenocarcinoma and primitive mesenchymal stroma. Foci of osteosarcoma, chondrosarcoma, or rhabdomyosarcoma are occasionally present.[5] It is a rare tumor with an incidence of <0.1% of resected lung cancers.[5] It mainly occurs in adults, and smoking does appear to be an important risk factor.[5] The histologically distinct, malignant glandular component resembles the developing fetal lung at an early gestational age with tumor cells that have been compared to an endometrioid carcinoma. The malignant cellular stromal component similarly has an embryonic appearance (Fig. 111-13). These tumors may have missense mutations in exon 3 of *CTNNB1*, which may be useful in diagnosis.[5] The prognosis is poor and correlates with stage.

PULMONARY NEUROENDOCRINE TUMORS—OVERVIEW

The 2021 WHO classification includes four tumor subtypes with neuroendocrine differentiation: carcinoid tumor (typical), carcinoid tumor (atypical), large cell neuroendocrine carcinoma, and small-cell carcinoma.[5] Collectively, these neuroendocrine tumors represent about 25% of all primary pulmonary carcinomas, with small-cell carcinoma being by far the most common (nearly 80% of neuroendocrine tumors). Typical carcinoid tumors, despite their low incidence, are well represented in surgical series but the relative rarity of atypical carcinoid tumors (<1% of all lung cancers) and the lower incidence (<20%) and inadequate representation of large cell neuroendocrine carcinoma in surgical series have made it more difficult to establish treatment guidelines and prognosis for those entities. Historically, the recognition of "neuroendocrine differentiation" was based on morphologic characteristics as assessed by traditional light microscopy and hematoxylin and eosin sections. The subsequent introduction of electron microscopy and then the widespread use of immunohistochemistry (which is the current standard in routine clinical practice) led to a broader identification of "neuroendocrine differentiation" and, inevitably, debates about classification, therapeutic implications, and prognosis ensued. As is to be expected with any framework for classification, the WHO classification for neuroendocrine tumors is not without some controversy and practical difficulties. Although it has been intellectually appealing to view the pulmonary neuroendocrine tumors

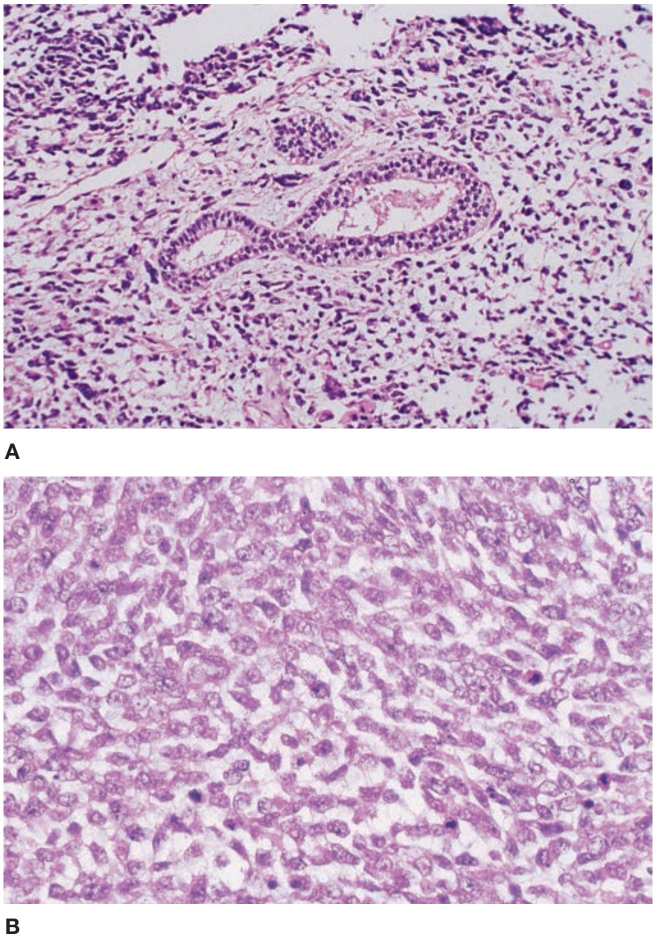

Figure 111-13 **A.** Pulmonary blastoma, showing a characteristic endometrioid-type gland, composed of cells with clear cytoplasm and basally oriented nuclei (H&E, 200×). **B.** Malignant stroma in a pulmonary blastoma (H&E, 400×).

along a continuous spectrum from low grade (typical carcinoid) to intermediate grade (atypical carcinoid) to high grade (large cell neuroendocrine carcinoma and small-cell carcinoma), the data indicate that there are major epidemiologic, clinical, histologic, genetic, and prognostic differences between carcinoid tumors and the high-grade neuroendocrine carcinomas.[5,39] Large cell neuroendocrine carcinoma is defined as a non–small-cell carcinoma with a distinct morphologic appearance and immunohistochemical evidence of neuroendocrine differentiation.[5] Leaving some occasional issues in diagnostic reproducibility aside, this entity challenges the traditional separation of the two high-grade neuroendocrine tumors into small-cell carcinoma and non–small-cell carcinoma (large cell neuroendocrine carcinoma) for treatment purposes, as some authors have suggested that treatment paradigms for small-cell carcinoma be similarly applied to the management of large cell neuroendocrine carcinoma.[40,41]

It is also important to note, based on surgically resected series of small-cell lung carcinoma and large cell neuroendocrine carcinoma that up to about 25% of these tumors will have other histologic components of non–small-cell lung carcinoma such as adenocarcinoma or squamous cell carcinoma. These tumors are designated as "combined" small-cell lung carcinoma or large cell neuroendocrine carcinoma.[5]

CARCINOID TUMORS

The overall incidence of carcinoid tumors is less than 2% of all lung cancers.[5] The 2021 WHO classification recognizes two distinct subtypes of carcinoid tumor—typical carcinoid tumor and atypical carcinoid tumor.[5] Both tumors are recognized by their low-power architectural pattern and characteristic cytologic features that are familiar to pathologists and are similar in appearance to carcinoid tumors that occur in other primary sites such as the gastrointestinal tract. However, in contrast to the terms low-grade or intermediate-grade or well-differentiated neuroendocrine carcinoma that are now used in extrapulmonary sites, carcinoid tumor has been retained in the lung tumor nomenclature because of its familiarity to clinicians and because of the well-established clinical behavior associated with the terminology and criteria for diagnosis. Although ki-67 has been incorporated into the diagnosis of neuroendocrine tumors in extrapulmonary sites, mitotic count and the presence of necrosis have proved to be the most robust and reliable features for classification of pulmonary carcinoid tumors. The mitotic activity is expressed as the number of mitoses per 2 mm^2. Since mitotic count and the consequent tumor classification are based on a resection specimen, it is not possible to reliably separate an atypical carcinoid from a typical carcinoid tumor on the basis of a small biopsy or to apply this criterion to a cytology specimen. The distinction may not affect subsequent prognosis if the tumor is amenable to surgical management, but it may impact subsequent prognosis if the patient is not resected and the tumor remains largely unsampled. The 2021 WHO classification recommends the generic topline diagnosis of "carcinoid tumor NOS" for any small sample or sampling from a metastatic site with a notation of mitotic count and ki-67. Although these criteria cannot be used for definitive classification, it is felt that treating oncologists might find the information of some utility.

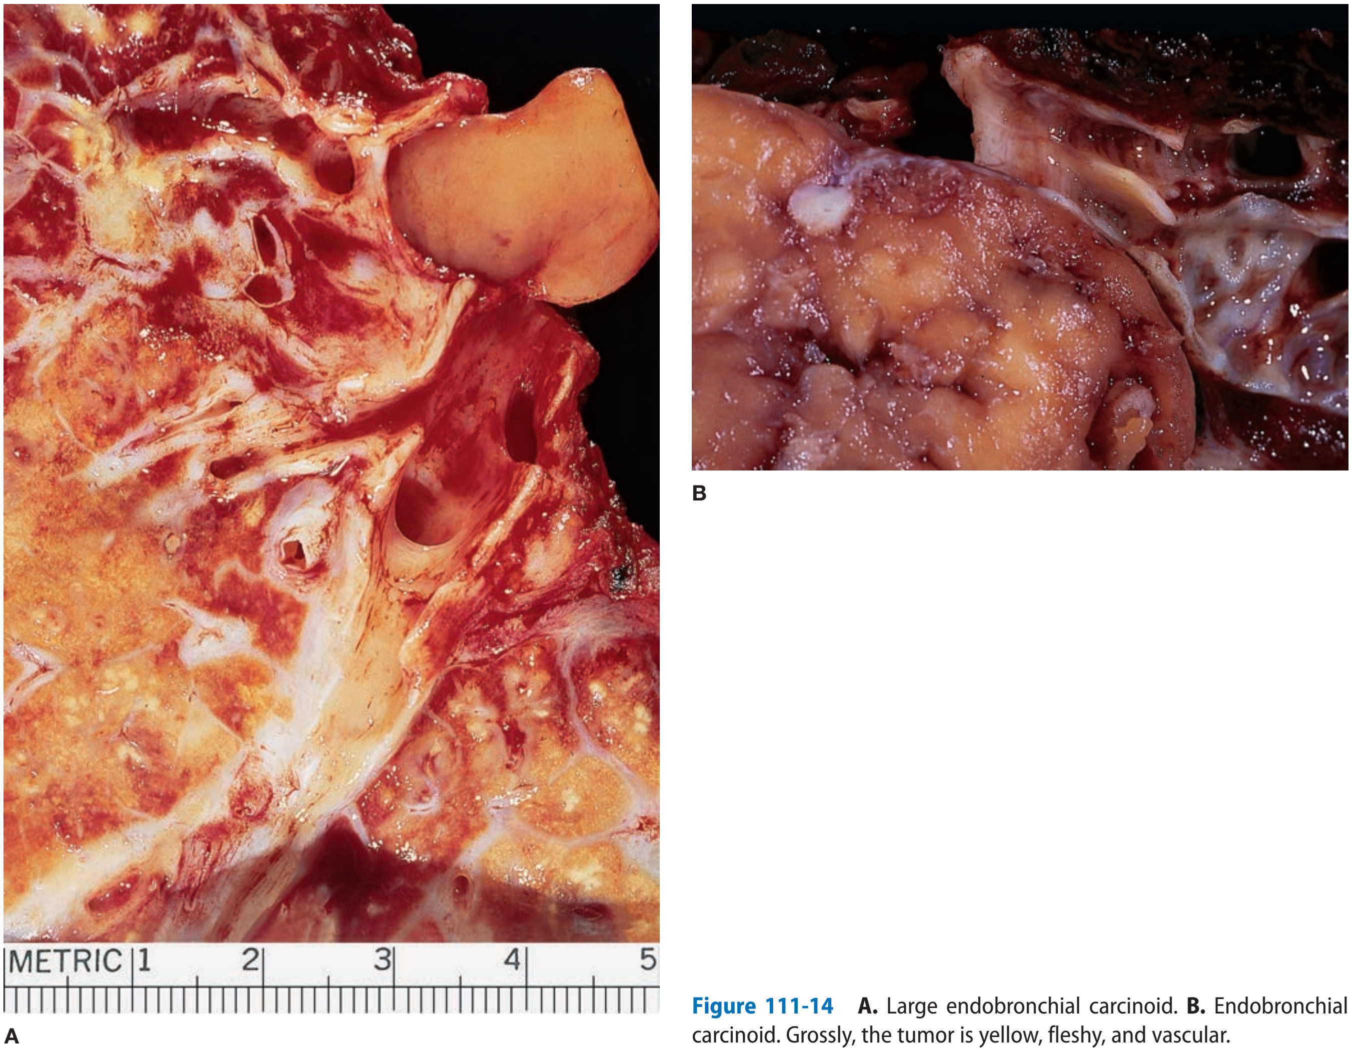

Figure 111-14 **A.** Large endobronchial carcinoid. **B.** Endobronchial carcinoid. Grossly, the tumor is yellow, fleshy, and vascular.

Typical Carcinoid

Typical carcinoid tumors can be divided into central and peripheral variants. Both variants can be asymptomatic, but central carcinoids, which characteristically grow as an endobronchial mass, may present clinically with recurrent pneumonias or hemoptysis. Typical carcinoid tumors are not associated with tobacco use, but there is an association with multiple neuroendocrine neoplasia (MEN)1 syndrome in about 5% of cases, and screening for pulmonary carcinoids with CT imaging is recommended in patients with MEN1.[42] The incidence of bronchial carcinoid tumors with carcinoid syndrome at presentation is low (1%–3%), usually occurring in the presence of metastatic liver disease.[43] Cushing syndrome due to ectopic production of ACTH is similarly rare.

Central carcinoids grossly appear as yellow or fleshy polypoid masses (Fig. 111-14). The tumor usually has a significant exophytic endobronchial component, but the tumor can infiltrate between cartilaginous rings to extensively involve the bronchial submucosa. The tumor cells form diverse patterns such as organoid nests, trabeculae, insular islands, ribbons, or rosette-like arrangements. Carcinoids can also have papillary, sclerosing, follicular, and glandular patterns. The tumor cells are generally uniform in appearance and have a low nuclear:cytoplasmic ratio with round to oval nuclei and eosinophilic cytoplasm (Fig. 111-15). The tumor cells have characteristic neuroendocrine tumor chromatin that is finely granular or classically described as "salt and pepper."

Peripheral carcinoids are frequently subpleural and can be associated with a scar (Fig. 111-16A). Unlike the cells of central tumors, which are usually round or polygonal in shape, the tumor cells of peripheral carcinoids tend to have prominent spindle cell features (Fig. 111-16B). These fusiform cells have less cytoplasm than central tumors, but this feature should not be considered a sign of atypia. There is a subset of patients with one or more peripheral carcinoid tumors who have multiple tumorlets (defined as small neuroendocrine cell proliferations <0.5 cm) and diffuse idiopathic pulmonary neuroendocrine cell hyperplasia (DIPNECH). This neuroendocrine cell hyperplasia represents a preneoplastic condition. In addition, a significant complication for this subset of patients is airway fibrosis, which can progress to severe obstructive lung disease.

The pathologic attributes of typical carcinoid tumors have been examined in numerous histologic, immunohistochemical, and molecular studies. The only consistent prognostic indicators have proved to be mitotic rate and necrosis. The current 2021 WHO criteria for the diagnosis of typical carcinoid tumor require less than 2 mitoses per 2 mm^2 of viable tumor and no necrosis. Cytologic atypia, increased cellularity, and lymphovascular invasion are not predictive features. Although typical carcinoid tumors have a generally excellent prognosis, with the majority presenting as early-stage tumors that can be completely resected, it is critical to understand that typical carcinoids are low-grade but malignant tumors. The incidence of lymph node metastasis is in the range of 10% to 15%, with a 3% to 5% incidence of distant metastasis at presentation.[44] The presence of lymph node metastases, however, is not used for classification of typical versus atypical carcinoid tumor. The current TNM classification is used for staging bronchopulmonary carcinoid tumors.

Atypical Carcinoid

The term *atypical carcinoid* was first introduced by Arrigoni and colleagues in 1972.[45] Twenty-three tumors were described that appeared to have a general resemblance to carcinoid tumors but that also had a focally disorganized growth pattern, areas of tumor

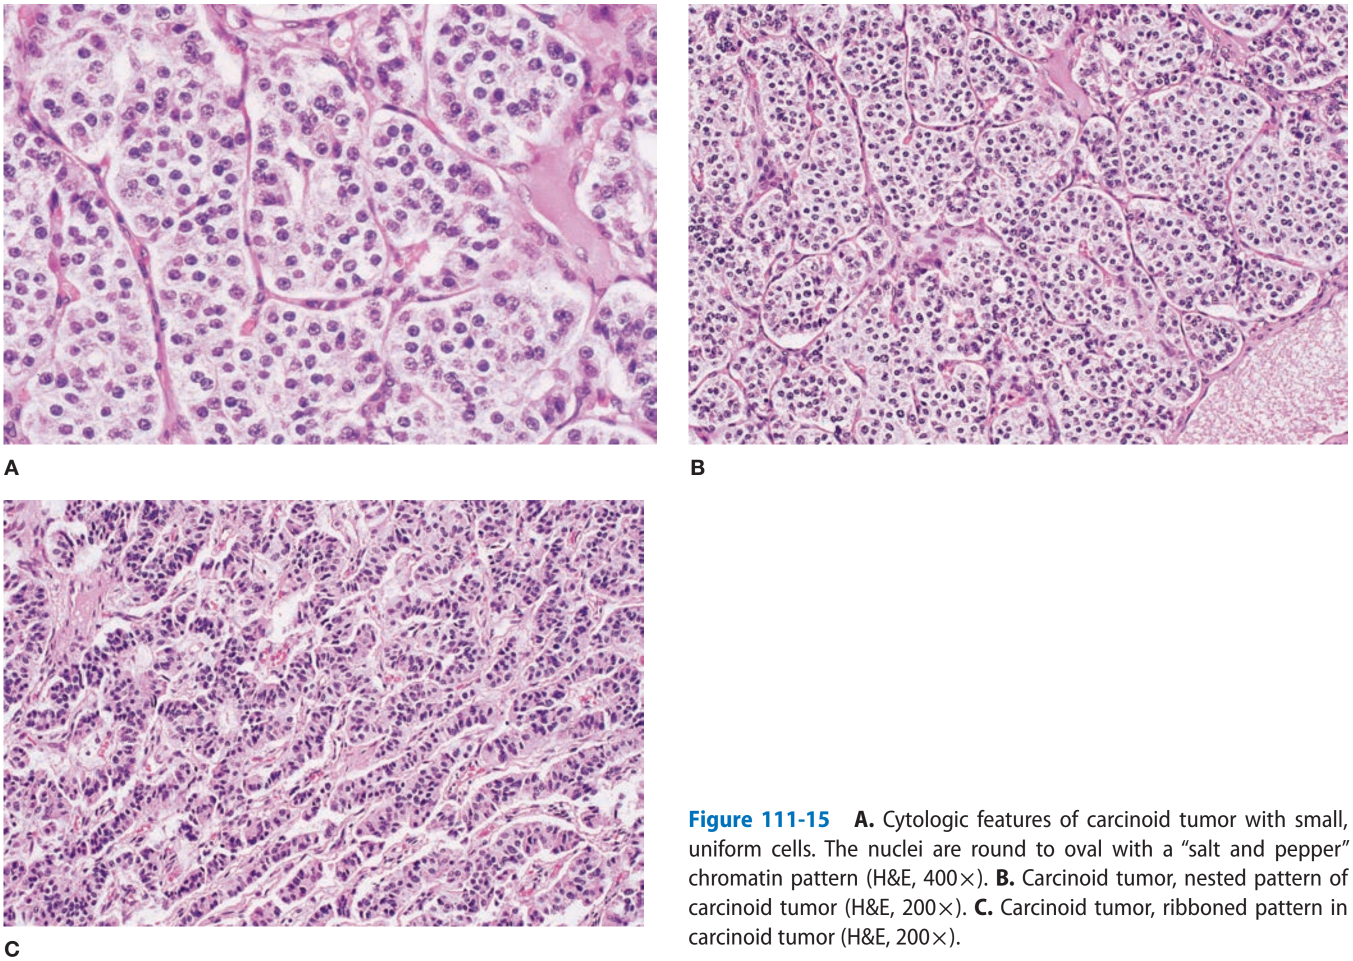

Figure 111-15 **A.** Cytologic features of carcinoid tumor with small, uniform cells. The nuclei are round to oval with a "salt and pepper" chromatin pattern (H&E, 400×). **B.** Carcinoid tumor, nested pattern of carcinoid tumor (H&E, 200×). **C.** Carcinoid tumor, ribboned pattern in carcinoid tumor (H&E, 200×).

necrosis, increased mitoses, and cellular pleomorphism. Dissension was immediately generated by the use of the word "atypical," given the aggressive biologic behavior in their series. Many other terms were introduced into the literature in the 1980s as more published reports detailing this entity appeared. The tumors described in these initial papers were a heterogeneous group, in part due to the subjective interpretation of features such as "architectural distortion." In defending atypical carcinoids as a distinct clinicopathologic entity, Travis et al.[46] emphasized that the overall architecture should be that of a recognizable carcinoid tumor with a predominantly organoid growth pattern. In the 2021 WHO classification, an atypical carcinoid tumor is defined as a carcinoid tumor with between 2 and 10 mitoses per 2 mm^2 and/or with foci of necrosis.[3] The necrosis in these tumors is usually punctate (Fig. 111-17), and one should be careful to exclude the possibility of a large area of necrosis that is secondary to a previous fine-needle aspiration or needle biopsy. Although cytologic atypia, lymphovascular invasion, nucleoli, increased cellularity, and disorganized architecture may be seen, these features are not a part of the classification system. Like typical carcinoid tumors, atypical carcinoid tumors can occur centrally as well as in the periphery. It is appropriate to consider atypical carcinoid tumors as an intermediate-grade malignant tumor with an increased capacity for progression. Atypical carcinoids have a higher incidence of lymph node metastases at presentation (about 50%) and of distant metastases at presentation (about 20%) than typical carcinoid tumors.[44]

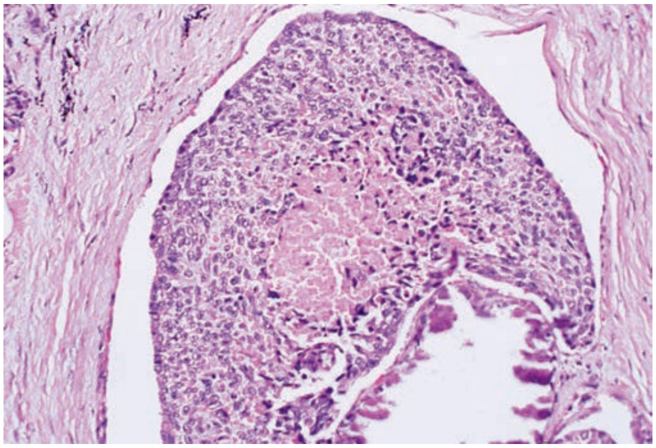

Figure 111-17 Central necrosis in an atypical carcinoid tumor (H&E, 200×).

Small-Cell Carcinoma of the Lung

The 2021 WHO classification defines small-cell carcinoma as a malignant epithelial tumor consisting of small cells with scant cytoplasm, finely granular nuclear chromatin, and absent or inconspicuous nucleoli, with a high mitotic count and frequent necrosis.[5] The tumor cells can be round, oval, or spindle shaped with poorly defined cell borders. The criterion for cell size is given as "usually less than the size of three small resting lymphocytes," but there is no absolute criterion for cell size and cell size can vary from less than the diameter of three resting lymphocytes (10 µm) to that of a larger tumor cell (45 µm) depending on the type of specimen, the quality of fixation/processing, and inherent tumor heterogeneity.[47–49] Nuclear molding is commonly seen, as is crush artifact with basophilic nuclear DNA encrustation of the vessel walls (Azzopardi effect). There is usually a high mitotic rate, averaging over 60 mitoses per 2 mm^2, but a significant mitotic rate may not be discernible in some small biopsy cases.[50] Extensive necrosis and numerous apoptotic cells are frequently seen but again may be absent in smaller biopsies (Fig. 111-18). While this definition

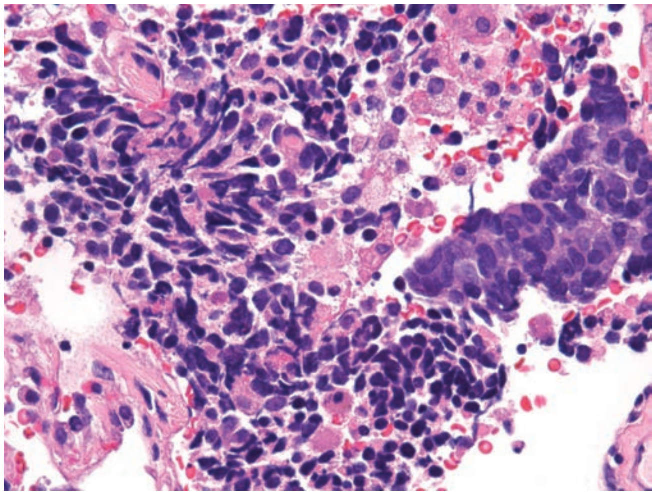

Figure 111-18 Small cell carcinoma. Classic tumor cell appearance with scant amounts of cytoplasm, hyperchromatic nuclei, nuclear molding, crush artifact, and necrosis. (H&E, 400×).

can be simply summarized, and the most classic appearance of small-cell carcinoma easily recognized with a high degree of interobserver agreement, diagnostic difficulties and issues of reproducibility do occur even among experts.[51] Some of these difficulties are related to the sampling problems inherent in the small biopsies that are obtained by fiberoptic bronchoscopy, and are further discussed in the section on small biopsies. Some of these difficulties are related to the qualitative rather than quantitative criteria that have been set forth as distinguishing features between small-cell carcinoma and large cell neuroendocrine carcinoma and will be further discussed in the section on large cell neuroendocrine carcinoma.

Small-cell lung carcinoma has decreased in incidence in the United States but it is still the most common of the pulmonary neuroendocrine tumors.[44] A significant smoking history is present in the vast majority of cases, such that the diagnosis of small-cell carcinoma should be seriously reconsidered in a patient without current or former heavy tobacco use. There are several different presentations that are familiar to most clinicians. Patients may present with pulmonary symptoms related to a large central mass that include cough, wheezing, dyspnea, and hemoptysis. Mediastinal extension may cause superior vena cava syndrome, recurrent laryngeal nerve paralysis, or dysphagia. Constitutional symptoms such as pain, decreased appetite, and weight loss are also common. A significant number of patients present with widespread metastases involving the liver, brain, bone, and adrenal glands. Paraneoplastic syndromes include the syndrome of inappropriate secretion of antidiuretic hormone, Eaton–Lambert syndrome, and ectopic Cushing syndrome. Despite the fact that less than 10% of patients with small-cell carcinoma limited to the lung are surgical candidates, the International Association for the Study of Lung Cancer (IASLC) staging project recommends and adopted the TNM staging system rather than the traditional limited- versus extensive-stage disease that has been used for staging small-cell carcinoma.[52] The College of American Pathologists (CAP) protocol for the examination of resected pulmonary specimens includes small-cell carcinoma and can be used as a template for pathologic evaluation as with non–small-cell carcinomas.

Small-cell carcinoma can present as a solitary pulmonary nodule, and early-stage small-cell carcinomas are occasionally resected. In the descriptions of surgically resected small-cell lung carcinomas, the gross appearance does not differ significantly from many other lung carcinomas.[49] The tumors are described as well circumscribed and often lobulated, with others as endobronchial and some as subpleural. The cut surface is described as white to tan to yellow and gray, with necrosis recorded in only a small number of cases.

In addition to other neuroendocrine tumors, the differential diagnosis of small-cell carcinoma might include nonspecific chronic inflammation, other small "round blue cell tumors," and poorly preserved, often necrotic non–small-cell lung carcinomas. The general use of immunohistochemistry in the differential diagnosis of lung tumors is discussed in a separate section, but two points deserve to be emphasized here. One point is that a positive TTF-1 stain cannot be used to support a diagnosis of a primary pulmonary small-cell carcinoma or to exclude a metastatic small-cell carcinoma from an extrapulmonary primary.[53] The second point is that it is a mistake to rely on neuroendocrine markers alone for the diagnosis of small-cell carcinoma. Not only are neuroendocrine markers negative in about 10% of small-cell carcinomas, but other tumors within the differential diagnosis may be positive for neuroendocrine markers. The difficulties that can be encountered in separating small-cell carcinoma from carcinoid tumors and other non–small-cell carcinomas in a small biopsy are discussed in greater detail in a separate section, as is the distinction from large cell neuroendocrine carcinoma. But in general, it might be considered that the name itself, "small-cell" carcinoma, has led to a relative overemphasis on cell size in comparison to other criteria. From a therapeutic point of view, the recognition of any small-cell component has significant clinical implications, but interpretative disagreements as to whether the tumor is a combined small-cell carcinoma (small-cell carcinoma mixed with any type of non–small-cell carcinoma component) or a pure small-cell carcinoma may not.

LARGE CELL NEUROENDOCRINE CARCINOMA OF THE LUNG

In 1991, Travis and colleagues[54] first proposed criteria for this entity, which was considered to be histologically distinct from atypical carcinoid tumor or small-cell carcinoma. A great deal of controversy ensued over that following decade and continues to some extent to the current time, although rapid advances in the molecular classification of lung tumors have shifted the focus away from pure morphologic characterization as the basis for treatment. As mentioned in the introduction to this section on pulmonary neuroendocrine tumors, one controversy centers on the reproducibility of the diagnosis of large cell neuroendocrine carcinoma. One study has demonstrated substantial agreement, at least among experienced lung pathologists.[51] In this study, a majority consensus diagnosis was achieved for 50% of the cases of large cell neuroendocrine carcinoma, which is no worse than other categories of lung tumors. However, there are a number of other studies that question the reproducibility of the diagnosis and have highlighted the considerable overlap in cell size and the substantial degree of subjective interpretation that is required for categorization.[49,55–58] Also problematic, as it is for other WHO lung tumor entities, is that the definition of large cell neuroendocrine carcinoma applies to resected tumors and not to smaller samples. A third controversy has focused on the clinical significance of the diagnosis, particularly in relationship to small-cell carcinoma. From an epidemiologic perspective, both tumors are associated with heavy tobacco use and both tumors can occur in combination with other non–small-cell lung cancers. Both tumors are aggressive high-grade neuroendocrine tumors and have a very poor prognosis.

Large cell neuroendocrine carcinoma is defined as "a high-grade non–small-cell carcinoma with neuroendocrine morphology and a mitotic count of >10 mitoses/2 mm^2, that expresses one or more neuroendocrine immunohistochemical markers."[5] Histologic features that suggest neuroendocrine differentiation include organoid nesting, trabecular, rosette-like, and palisading patterns. The cells are relatively large in size, often polygonal in shape, with moderate to abundant cytoplasm. The nuclear chromatin ranges from vesicular to finely granular. Nucleoli are frequent and often prominent (Fig. 111-19A). The presence of nucleoli tends to be a critical feature in the separation from small-cell carcinoma (Fig. 111-19B), but some large cell neuroendocrine carcinomas lack this criterion. As mentioned previously, neuroendocrine differentiation must be demonstrated by ancillary techniques such as immunohistochemistry. CD56, chromogranin, and synaptophysin are the three stains that are most frequently used together if there is sufficient tissue and are considered to be more specific than neuron-specific enolase, which is not recommended to use. For a tumor to be designated as a large cell neuroendocrine carcinoma, the tumor must have both neuroendocrine morphology and positive staining. Tumors that otherwise look like squamous cell carcinomas, adenocarcinomas, or large cell carcinomas but have focal neuroendocrine staining are not included in this definition and are not formally part of the WHO classification. *Combined large cell neuroendocrine carcinoma* refers to a large cell neuroendocrine carcinoma with components of another non–small-cell carcinoma such as, for example, squamous cell carcinoma or adenocarcinoma.

The low incidence of the tumor (estimated as 3% of non–small-cell carcinomas) has resulted in a lack of robust evidence for

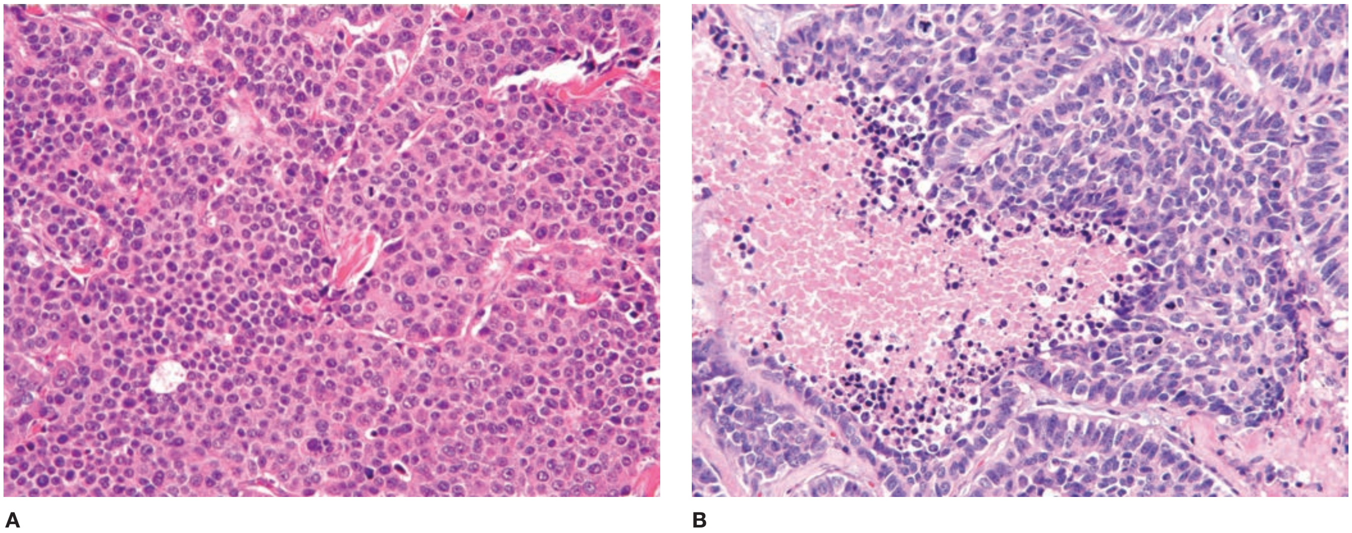

Figure 111-19 Side-by-side comparison of large cell neuroendocrine carcinoma **(A)** with small cell carcinoma **(B)**. The large cell neuroendocrine tumor cells have more cytoplasm and there are more prominent nucleoli. The small cell carcinoma tumor cells have less cytoplasm and the nuclear chromatin is finely granular. (H&E, 200×).

stage-based treatment strategies.[44] What can be concluded is that the molecular genotype and phenotype of large cell neuroendocrine carcinoma and small-cell carcinoma in some data subsets are similar enough to support at least consideration of extrapolation from treatment paradigms for small-cell carcinoma and, as has been suggested, to include unresectable disease large cell neuroendocrine carcinoma patients within clinical trials for small-cell carcinoma to obtain prospective data. It is anticipated that in the future these data may further clarify the clinical and pathologic distinction between these two high-grade neuroendocrine carcinomas.

SALIVARY GLAND–TYPE TUMORS

Mixed seromucinous glands are found in the tracheal and large bronchial submucosa and are believed to give rise to a variety of salivary gland–like tumors, histologically indistinguishable from their major salivary gland counterparts. The 2021 WHO recognizes six subtypes of malignant salivary gland tumors in the lung: pleomorphic adenoma, adenoid cystic carcinoma, epithelial–myoepithelial carcinoma, mucoepidermoid carcinoma, hyalinizing clear cell carcinoma, and myoepithelioma (as well as myoepithelial carcinoma).[5] Other salivary gland–like tumors such as acinic cell carcinoma or carcinoma ex pleomorphic–mixed tumor do occur in the lung but are exceptionally rare. Salivary gland carcinomas represent less than 1% of all lung carcinomas, with mucoepidermoid carcinoma and adenoid cystic carcinoma being the most common subtypes.[5] Although uncommon, their distinctive morphology, growth pattern, and clinical presentation make these salivary gland–type tumors of the lung an important subgroup of malignant epithelial tumors of the lung. In all instances of suspected primary salivary gland–type tumors, it is important to exclude metastasis from an extrathoracic primary, particularly from the head and neck.

■ Adenoid Cystic Carcinoma

Adenoid cystic carcinoma is the most common of the tracheobronchial gland tumors but is still quite rare, representing less than 1% of all primary lung tumors.[5] There is no association with smoking. The vast majority of cases originate within the bronchial lumen, and the typical presenting symptoms such as wheezing, progressive dyspnea, stridor, cough, and hemoptysis reflect this intraluminal tumor growth. Unlike carcinoid tumors and mucoepidermoid carcinomas, which usually present as intraluminal endophytic masses, adenoid cystic carcinomas have a more variable growth pattern. Some tumors are grossly nodular with minimal invasion of the bronchus, whereas others have a mixed nodular/infiltrative or predominantly infiltrative growth pattern (Fig. 111-20A,B). More infiltrative tumors appear as small nodules within the airway or cause a generalized constriction of the airway. There may be lymph node involvement, usually by direct extension, and higher-grade tumors have a tendency to radially spread into the adjacent parenchyma rather than along the airways.

The microscopic level of invasion nearly always exceeds that which is grossly apparent. Negative resection margins often are difficult to achieve. Complete resection may be quite difficult and can require multiple frozen sections to confirm clear surgical margins. The tumor cells are small with a relatively high nuclear:cytoplasmic ratio, but nuclear pleomorphism and mitoses are rare. Characteristic mucinous cysts of varying size are present within the tubular and cribriform patterns (Fig. 111-20C). Poorly differentiated tumors have a significant component of solid tumor nests. As is characteristic of their salivary gland counterparts, adenoid cystic carcinomas are notorious for perineural spread. Long-term survival can be achieved with adequate resection, but local recurrence may occur even late (>10 years) following resection. The most common site of disseminated disease is the lung parenchyma, but extrathoracic metastases do uncommonly occur.[59] As with adenoid cystic carcinomas of the head and neck, *MYB-NFIB* gene fusion testing can be used to support the diagnosis.[60,61]

■ Mucoepidermoid Carcinoma

Mucoepidermoid carcinomas account for <1% of lung cancers.[5] Patients with this tumor may be asymptomatic, but it is far more common for patients to present with symptoms of bronchial obstruction due to the tumor's characteristic endobronchial location.[62] These symptoms include wheezing, cough, and hemoptysis, and patients may present with postobstructive pneumonia. The age at presentation varies, but almost half of the cases of mucoepidermoid carcinoma occur in patients under 30 years of age and it is common in the pediatric population. There is no significant association with tobacco use. Although the radiographic findings may be subtle and identified in retrospect, a solitary, centrally located mass with distal pneumonia or atelectasis is typical.

Mucoepidermoid carcinomas usually arise from segmental and subsegmental bronchi but can involve the trachea as well. The

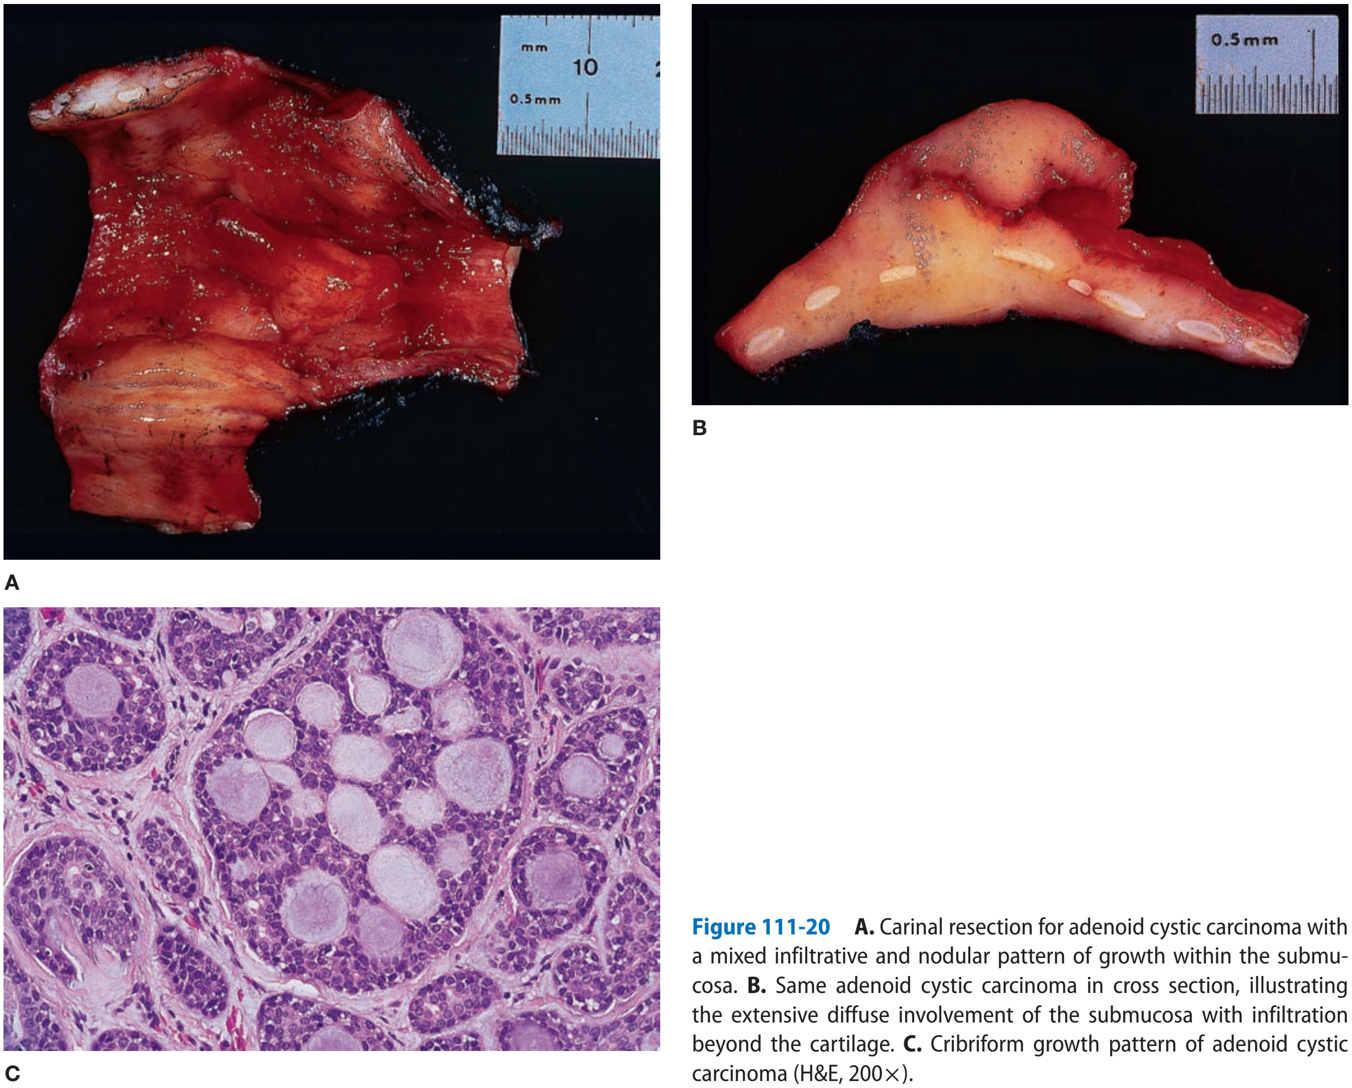

Figure 111-20 **A.** Carinal resection for adenoid cystic carcinoma with a mixed infiltrative and nodular pattern of growth within the submucosa. **B.** Same adenoid cystic carcinoma in cross section, illustrating the extensive diffuse involvement of the submucosa with infiltration beyond the cartilage. **C.** Cribriform growth pattern of adenoid cystic carcinoma (H&E, 200×).

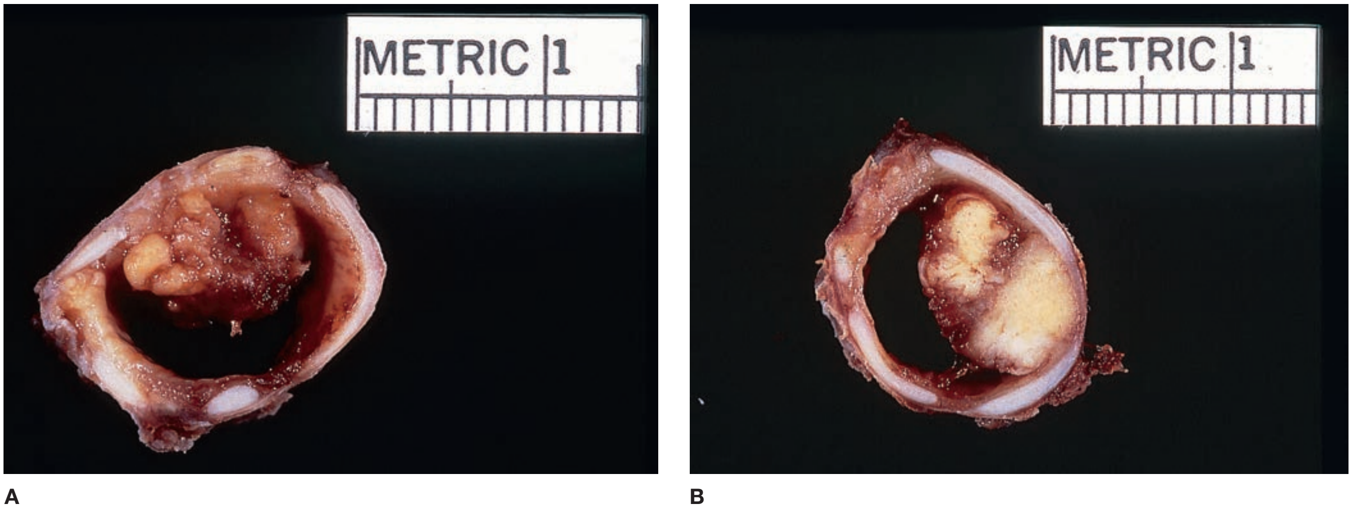
average size is about 3 cm, and the tumor grows as a polypoid mass with a tan or gray surface (Fig. 111-21A,B). On cross section, the tumor may appear more mucoid or cystic than the more common non–small-cell carcinomas of the lung. Histologically, mucoepidermoid tumors of the lung are separated into low- and high-grade tumors.[63,64] An "intermediate grade," which is used for tumors within the salivary gland, is not normally recognized within the WHO lung classification. The tumors are composed of a mixture of mucin-secreting cells, squamous cells, and what are termed "intermediate cells." The intermediate cells have a polygonal shape and eosinophilic cytoplasm but lack obvious squamous or glandular differentiation. The mucinous component consists of well-differentiated glands, with both intracellular and extracellular mucin (Fig. 111-21C). These tumors are TTF-1 negative. In low-grade tumors, the cells have minimal pleomorphism, rare mitoses, and minimal necrosis. Criteria for high-grade tumors include frequent mitoses, necrosis, and nuclear pleomorphism. High-grade mucoepidermoid carcinomas still retain a characteristic admixture of mucin-containing cells, squamoid cells, a central endobronchial location, and transitional areas from low-grade mucoepidermoid carcinoma. There should be no keratinization, squamous pearl formation, or in situ squamous cell carcinoma. These features, if present, are more consistent with a diagnosis of squamous or adenosquamous carcinoma. *CRTC1-MAML2* gene fusion testing can be used to support the diagnosis.[65]

The clinical behavior of these neoplasms had been controversial, mainly due to past ambiguities regarding the definition of high-grade mucoepidermoid carcinomas and their distinction from adenosquamous carcinomas. Low-grade tumors, which are usually confined to the bronchus, have an excellent prognosis following complete excision. High-grade tumors, which tend to invade the adjacent lung parenchyma, carry a worse prognosis and tend to behave in a manner similar to more common non–small-cell carcinomas. The data suggest that long-term clinical follow-up is indicated for these patients. Lymph node metastasis and incomplete resection are associated with a poor prognosis.[5]

■ Epithelial–Myoepithelial Carcinoma

The 2021 WHO classification defines epithelial–myoepithelial carcinoma as a biphasic tumor that consists of an inner layer of epithelial cells forming duct-like structures and an outer layer of myoepithelial cells (Fig. 111-22).[5] The tumor is extremely rare, accounting for less than 4% of primary salivary gland-type tumors of the lung.[5,66–68] Endobronchial tumors are most common, but the tumor may also arise within the lung parenchyma. There is a wide reported age range, and there are no known risk factors. Grossly the tumor is well circumscribed but unencapsulated, with a size range of 1.2 to 5.0 cm. Microscopically, the tumor consists of duct-like structures that are lined by a double layer of cells with an inner layer of cuboidal cells with eosinophilic cytoplasm and an outer layer of cells with predominantly clear cell cytoplasm. There is often eosinophilic material in the luminal spaces. The outer layer of cells and more solid components typically stain positively for SMA, S-100, p63, and



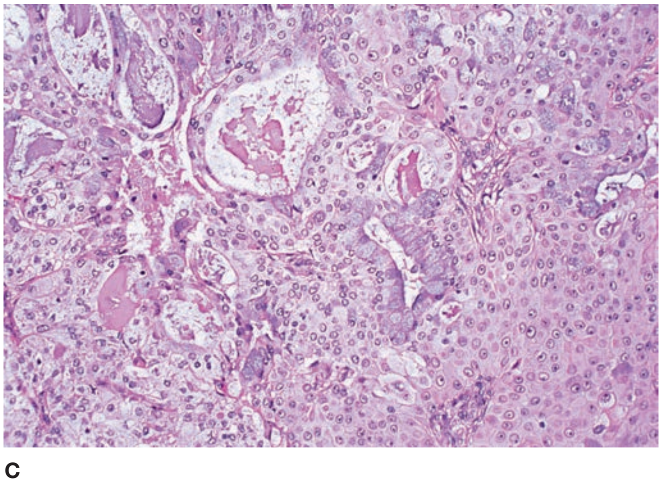


Figure 111-21 **A.** Left mainstem bronchus resection for endobronchial mucoepidermoid carcinoma. **B.** Same mucoepidermoid carcinoma tumor in cross section, demonstrating an attachment to the bronchus but invasion is limited to the superficial portion of the submucosa. **C.** Mucoepidermoid carcinoma. There are both well-differentiated mucinous glands *(left)* and intermediate cells *(right)* that have a polygonal shape and abundant eosinophilic cytoplasm (H&E, 200×).

calponin, which is characteristic of myoepithelial cells. The inner layer of tumor cells stains positively with cytokeratins (CAM5.2, AE1/3, CK7, and CK903) as well as EMA and TTF-1.[5] The positive TTF-1 staining is of interest in that other salivary gland–type tumors such as adenoid cystic carcinoma and mucoepidermoid carcinoma are reported to be TTF-1 negative. Most cases are low grade, with patients free of disease following complete surgical resection, but a minority of cases demonstrate lymph node involvement or recurrent disease.[66–68]

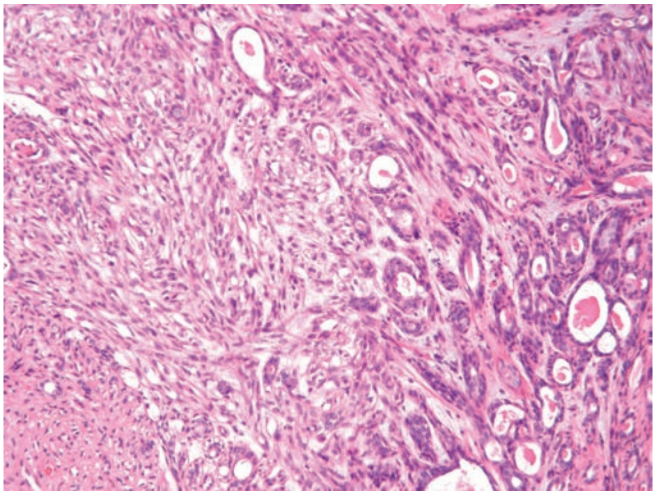

Figure 111-22 Epithelial–myoepithelial carcinoma. Tumor is composed of duct-forming epithelium and myoepithelial cells with a spindle cell morphology (100×).

ANCILLARY STUDIES

The lung is a common site for both primary tumors and metastases, and the pathologist must consider a broad differential diagnosis when analyzing a cytologic or tissue preparation. Ancillary studies typically are used to narrow the differential diagnosis or demonstrate differentiation. The appropriate use of ancillary studies is grounded in a well-formulated differential diagnosis based on the tumor's histologic appearance. The clinician contributes greatly by providing the details of a complete clinical history, thorough physical examination, and high-quality radiographic imaging. This helps direct the diagnostic work-up and avoids unnecessary tests that will delay the diagnosis or exhaust the tumor contained in that specimen. This latter consideration is particularly critical in the current era of molecular testing when the results are often needed in an expedited manner and *prior* to initiating treatment.

■ Histochemical Stains

The most commonly used histochemical stains in tumor evaluation are those that demonstrate intracellular mucins—periodic acid–Schiff (PAS) after diastase and mucicarmine—characteristic of adenocarcinomas. Mucin stains are typically performed on poorly differentiated carcinomas that appear as solid carcinomas lacking glandular differentiation but prove to have numerous mucin-positive tumor cells and therefore would be best classified as adenocarcinomas, solid type (Fig. 111-23). While helpful in some instances, mucin stains have a low sensitivity for glandular

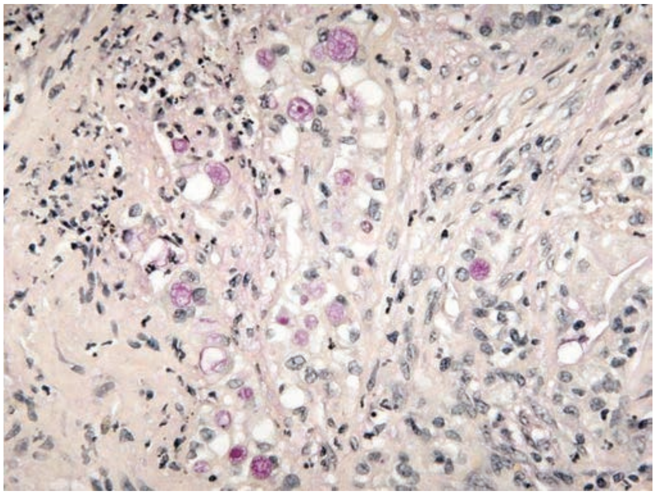

Figure 111-23 Positive mucin stain in a poorly differentiated non–small cell carcinoma with clear cell change, supporting the diagnosis of adenocarcinoma (400×).

differentiation (about 30%).[69] Although practice patterns vary somewhat, pathologists will often forego a mucin stain in small biopsies in an effort to preserve as much tissue as possible and do a limited panel of immunohistochemical stains instead. Alcian blue staining with hyaluronidase treatment can be used to distinguish the acid mucin of mesothelial cells from the epithelial mucin associated with adenocarcinomas, but its use has been supplanted by immunohistochemistry.

■ Immunohistochemistry

Immunohistochemistry is based on a primary antigen–antibody reaction and a secondary antibody–enzyme complex that interacts with a chromogen for a microscopically visible color reaction. Since its introduction into diagnostic pathology in the early 1980s, immunohistochemistry has become an integral part of tumor diagnosis. Unfortunately, there are very few antibodies that approach 100% sensitivity and specificity. As experts on immunohistochemistry have emphasized, it is diagnostically irrelevant to speak of overall sensitivity and specificity for a particular antibody. Rather it is more appropriate to speak of relative sensitivity and specificity within a particular differential diagnosis. This requires clinical interaction and morphologic expertise in generating a differential diagnosis in addition to critical assessment of the immunohistochemical results with appropriate controls. New antibodies are developed, evaluated, and introduced at a fairly constant rate. The following summary remarks are meant only as broad overview of current practice with the understanding that the field is constantly evolving and that all of the markers mentioned have utility both in and outside of the lung.[70]

Immunohistochemistry is often used in the work-up of an undifferentiated large cell carcinoma, usually to exclude melanoma and lymphoma, which can mimic a highly pleomorphic epithelial tumor. Within this differential diagnosis of an undifferentiated tumor composed of large cells, cytokeratin antibodies such as AE1/3, CAM5.2, and pancytokeratin are used to support the diagnosis of carcinoma. Cytokeratin antibodies will at least focally stain most non–small-cell carcinomas of all histologic subtypes, in addition to a wide variety of carcinomas from other primary sites. There are, however, potential pitfalls. Cytokeratin antibodies stain benign bronchial and alveolar epithelia, which can be entrapped within tumors and lead to a false-positive interpretation. Reactive mesothelial cells and malignant mesotheliomas are cytokeratin positive as well. Cytokeratin positivity, usually focal, also has been demonstrated in sarcomas and melanomas. S100, HMB45, SOX10, melan-A, MITF, and tyrosinase are markers of melanocytic differentiation; a panel using at least two or three of these is often employed when malignant melanoma is a strong consideration. Although sensitive, S100 is less specific for melanoma and stains other tumors, including those of neural origin and some adenocarcinomas of both primary pulmonary and extrapulmonary origin, such as the breast. The range of markers used to evaluate lymphoid neoplasms is extensive but include leukocyte common antigen (LCA), CD30, and B and T cell markers. There are antibodies to glycoproteins such as CEA, MOC31, and BerEP4, which stain a high percentage of adenocarcinomas, including adenocarcinomas of the lung. Recommended guidelines on the use of immunohistochemistry when the differential diagnosis includes malignant mesothelioma have been published and updated.[71] When the differential diagnosis centers on an epithelioid malignant mesothelioma versus adenocarcinoma, a panel of at least two affirmative markers for malignant mesothelioma and two affirmative markers for adenocarcinoma is recommended.

Immunohistochemistry is similarly used in the work-up of an undifferentiated small-cell carcinoma, usually to exclude melanoma and other "small round blue cell tumors" such as lymphoma, Merkel cell carcinoma, and other primitive neuroectodermal tumors. In this instance, attention to subtle differences in nuclear cytology, chromatin pattern, and mitotic activity is essential, as is a targeted immunohistochemical panel that might include (depending on the circumstances) pancytokeratin, synaptophysin, chromogranin, CD56, TTF-1, CK7, CK20, CD99, S-100, desmin, WT-1, LCA, myogenin, and TLE. Unusual clinical circumstances or radiographic imaging, particularly but not limited to a younger patient or a nonsmoker, should prompt consideration of a broad immunohistochemical workup as well as molecular tests for characteristic cytogenetic abnormalities for tumors such as a synovial sarcoma, desmoplastic small round cell tumor, NUT carcinoma, thoracic SMARCA4-deficient undifferentiated tumor, Ewing sarcoma, and rhabdomyosarcoma.

The use of immunohistochemistry has not eliminated the challenges of distinguishing a primary lung carcinoma from metastatic disease. There are only a limited number of instances in which immunohistochemical stains are useful in differentiating a pulmonary primary from a metastatic tumor. With the exception of thyroglobulin for the majority of thyroid tumors and prostate-specific antigen or NKX3.1 for the majority of prostatic adenocarcinomas, many other antibodies have too much overlap in specificity to be conclusive. There has been some qualified success in instances when the differential diagnosis includes other common solid organ malignancies such as breast or gastrointestinal carcinomas. Staining with a panel of antibodies to bolster one's diagnostic certainty in the differential diagnosis of primary lung carcinoma versus metastasis can certainly enhance diagnostic accuracy. Fundamentally, however, this type of immunohistochemical analysis remains an exercise in probabilities and may not be sufficient for certain clinical circumstances. It is most often the case that new markers are introduced into the literature with initial reports of high sensitivity and specificity. After a time, with additional studies and incorporation into daily practice, more exceptions appear. A good example is TTF-1. On average, TTF-1 stains about 75% of primary pulmonary adenocarcinomas, although the percentage is lower in more poorly differentiated tumors, some subtypes of adenocarcinoma, and better-differentiated neuroendocrine tumors.[31] It was initially believed that the only extrapulmonary tumor that was as frequently positive for TTF-1 was thyroid carcinoma. Now there are reports of TTF-1 positivity in extrathoracic tumors that would not be expected—such as ovarian epithelial tumors—making the marker less specific than was initially asserted although often still useful.[31] The same can be said of gastrointestinal profile panels that use CK7, CK20, TTF-1, Napsin A, and CDX2 to support a luminal GI primary. Although many GI primaries will have a CK20, CDX2 positive and CK7, TTF-1, Napsin A negative staining pattern, a small subset of primary lung tumors with an "enteric" differentiation will show an overlapping staining pattern.[72] Whether "molecular profiles" will be able to improve diagnostic accuracy or supplant the relatively rapid turnaround time and low cost of immunohistochemistry remains to be seen.

As discussed in the section on pulmonary neuroendocrine tumors, the artifacts that are often present in small samples can make it difficult to separate out small-cell carcinoma from other non–small-cell carcinomas or to apply the criteria for separating out carcinoid tumors from the higher-grade neuroendocrine carcinomas. In addition to some of the other immunohistochemical stains mentioned for supporting neuroendocrine differentiation (synaptophysin, chromogranin, CD56, and INSM1), an extended panel might also include CK5/6, p40, and TTF-1 to exclude the possibility of a basaloid or small-cell variant of squamous cell carcinoma.[73] The proliferation marker ki-67 is routinely used in smaller specimens as a surrogate for identifying mitoses, which may be absent or infrequent. Although not completely standardized or reproducible, an increased proliferation index can be helpful in favoring a lower- or higher-grade neuroendocrine tumor.[50,74]

The need for a more precise classification of poorly differentiated non–small-cell carcinoma into squamous or nonsquamous histology has further expanded the use of immunohistochemistry within pulmonary pathology. A significant proportion of small biopsies (and some large resections) will not have obvious evidence of squamous differentiation, as defined by keratinization or intercellular bridges, or obvious features of adenocarcinoma, as defined by gland formation or intracellular mucin. In these instances when the tumor cells are arranged in solid nests and there is no specific evidence of differentiation, a panel of immunohistochemical stains can be used for further subclassification. There are numerous studies that have looked at the utility of immunohistochemistry in reducing the category of "non–small-cell lung carcinoma, not otherwise specified" and the minimum number of stains needed for evaluation. The latter point, of using the least number of stains with the most specificity and sensitivity, is not a trivial issue in the usual case of an advanced-disease patient who will have an initial biopsy that will likely be triaged for targeted therapy. At the current time, the data support at minimum a panel that includes TTF-1, CK5/6, and p40, with addition of stains such as Napsin A or CK7 if there is sufficient tissue (Fig. 111-24A–D).[68,75–77] Beyond using evidence to construct the best limited immunohistochemical panel to determine differentiation, other techniques such as dual-antibody staining cocktails can reduce the amount of tissue used (Fig. 111-25). As discussed in greater detail in the following section, processing decisions must be

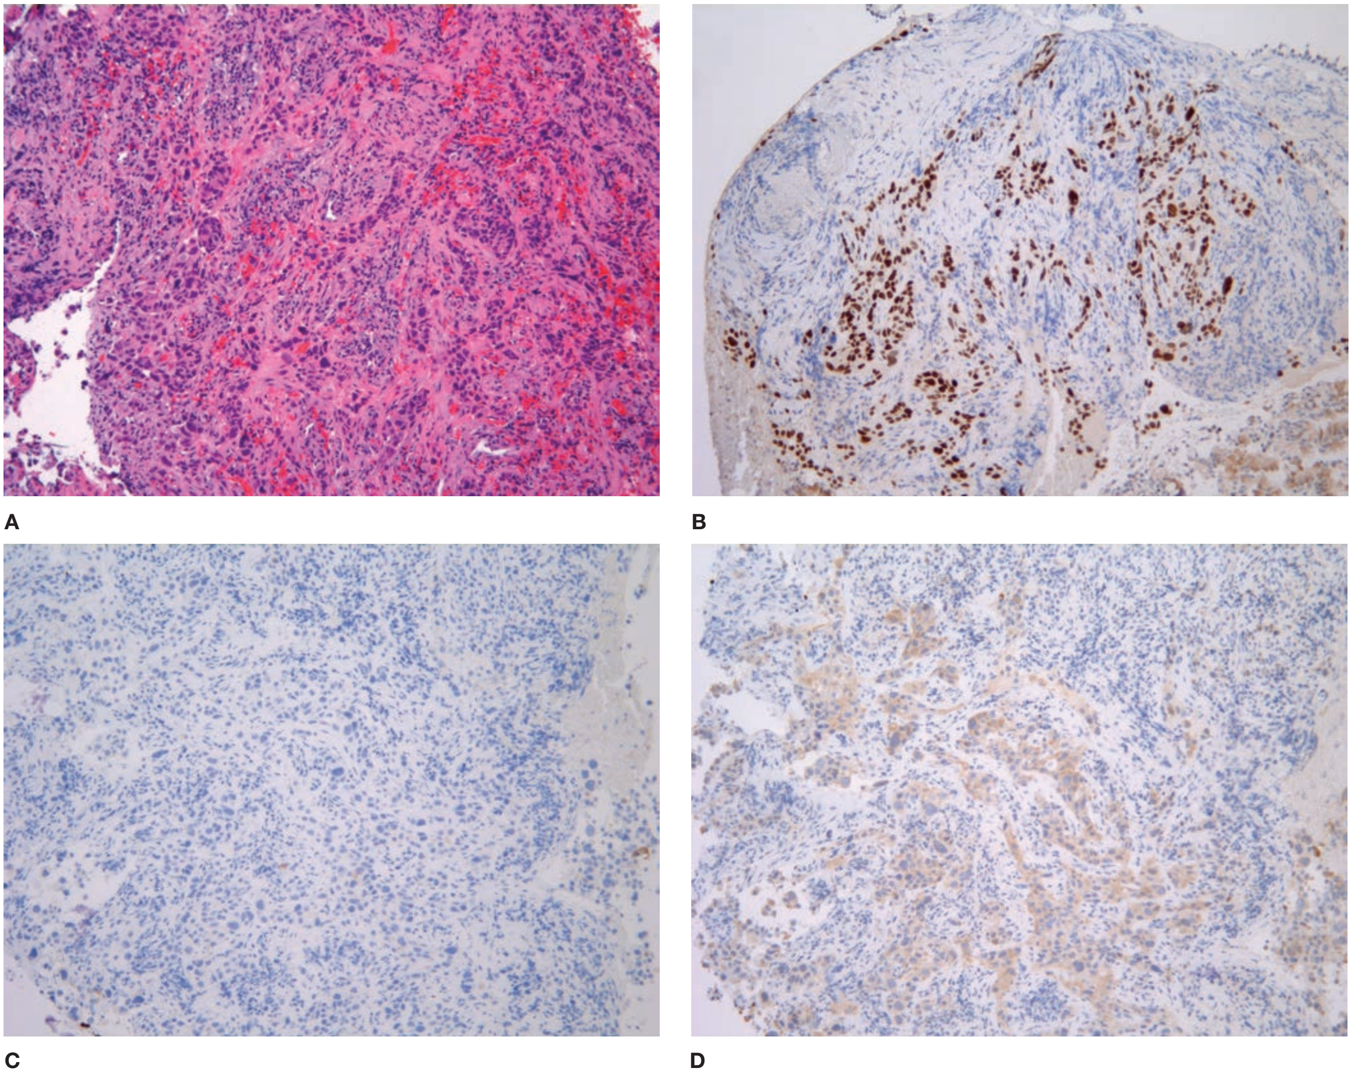

Figure 111-24 Small biopsy showing poorly differentiated non–small cell carcinoma and immunohistochemical stains supporting the diagnosis of pulmonary adenocarcinoma. **A.** H&E (100×). **B.** TTF-1 antibody positive (100×). **C.** CK5/6 antibody negative (100×). **D.** p63 antibody negative in tumor nuclei (100×).

made up front to ensure that there is sufficient material for diagnosis, immunohistochemical stains if necessary, and residual tissue for molecular testing.

The increased use of immunohistochemistry for histologic subclassification has generated debate, particularly in the context of clinical trials for advanced disease patients, as to what exactly it means—biologically, therapeutically, and prognostically—for a tumor to have only immunohistochemical evidence of differentiation. These issues were further complicated by the conspicuous historic lack of any standard nomenclature for small biopsies. The 2021 WHO classification includes terminology for small biopsies/cytology specimens in these instances that should help in the adoption of standardized terminology in general practice and within academic medical centers.[5]

ADEQUACY OF SMALL SPECIMENS FOR DIAGNOSIS, TREATMENT, AND MOLECULAR ANALYSIS

Small specimens occupy a central role in the majority of patients with lung cancer—often at multiple time points during the course of their disease—and the clinical relevance of these small specimens has led to a “paradigm shift” in the way these small specimens are processed and interpreted.[78] Bronchoscopic biopsies with or without endobronchial ultrasound guidance, fine-needle aspiration, and body fluid cytologic examination are all acceptable as minimally invasive procedures for the initial diagnosis of a primary lung carcinoma or to document metastasis. With the emerging emphasis on the importance of histologic subtyping in non–small-cell lung cancer and the need for molecular analysis for “personalized” or “precision” medicine, the debate in recent years had focused on whether small specimens are adequate for these purposes. Numerous studies have now established that a variety of specimens, ranging from small biopsies to cytology cell blocks to cytology touch imprints or aspirates, are potentially suitable for molecular testing and the practical considerations for testing have been recently and comprehensively reviewed.[79] The essential point is that small diagnostic specimens must be handled carefully from the outset of any procedure with the understanding that the specimen may be the only specimen available for molecular analysis. Within each specific practice setting, an algorithm should be established that emphasizes the need for communication between the pathologist and the clinical care team *before* the specimen is processed.[80] This clinical information should include such information as whether the biopsy is for initial diagnosis, whether the patient is a candidate for surgical resection, whether the patient is a candidate for targeted therapy, whether the biopsy is for molecular prioritization in a patient with an established diagnosis of lung cancer, or whether the biopsy is a repeat biopsy for resistance testing. All of this information will in turn allow the pathologist to communicate with molecular and histology laboratories to ensure that the specimen is appropriately triaged and that the optimal material is selected for diagnosis, ancillary immunohistochemical testing, and molecular prioritization.

CONCLUSION

In addition to the clinicopathologic features and histologic subtyping of primary pulmonary carcinomas, recent changes in tumor classification and sample evaluation have been reviewed. The pathologist makes a critical contribution to the management and treatment of lung carcinoma, but the final pathologic interpretation should not be rendered in a clinical vacuum. It is incumbent upon the clinician caring for the patient to be sure that the pathologist has the benefit of complete clinical information. Nowhere is this clinical information and communication more critical than in the processing of small specimens in this era of personalized medicine. The inclusion of the pathologist as an integral part of what is now a multidisciplinary evaluation team for a thoracic malignancy enhances the quality of care for the individual patient and refines the general practice of thoracic oncology.

CHAPTER 112

Clinical Evaluation, Diagnosis, and Staging of Lung Cancer

A. Cole Burks
M. Patricia Rivera

INTRODUCTION

Patients who present with suspected lung cancer require a detailed clinical evaluation followed by noninvasive testing and invasive procedures to establish both the histopathologic diagnosis as well as disease stage. Historically, great emphasis has been placed upon the differentiation of small-cell lung cancer (SCLC) from non–small-cell lung cancer (NSCLC). SCLC, which accounts for 13% of bronchogenic carcinomas, is histologically and clinically distinct from NSCLC.[1] NSCLCs comprise clinically, pathologically, and molecularly diverse tumors that respond to different therapeutic agents based on specific histologic phenotypes and molecular characteristics.

The clinician evaluating the patient with suspected lung cancer must take into account several factors, including the likelihood of SCLC versus NSCLC, probability of metastatic disease, comorbid illness, functional status, presence of paraneoplastic syndromes, and treatment preferences of the patient. Good decision-making regarding appropriate diagnostic test selection must incorporate (1) careful assessment of pretest probabilities based upon clinical evaluation and initial radiographic features, and (2) understanding of specific test characteristics. The main objectives of the diagnostic and clinical staging evaluation are to obtain adequate tissue to establish the histopathologic diagnosis and, when indicated, molecular and diagnostic biomarker testing screening for actionable oncogenic driver mutations and programmed death ligand 1(PD-L1) expression, and to ascertain the extent of disease to determine candidacy for specific therapies. These twinned goals should be accomplished in the safest, least invasive, and most cost-effective manner possible.

INITIAL CLINICAL EVALUATION

A detailed history and physical examination are of key importance in the assessment of the patient's overall health status and medical appropriateness for specific therapies.[2] Certain comorbid conditions may reduce therapeutic options. Limited cardiopulmonary reserve may preclude surgical intervention. A thorough history can also assist a physician in determining the overall extent of disease. At the time of presentation, it is most useful to consider the clinical stage using the International Association for the Study of Lung Cancer (IASLC) 8th edition of the tumor, node, and metastasis (TNM) classification system (Table 112-1); pathologic stage is established only after surgical resection.[3]

TABLE 112-1 TNM Staging System for Lung Cancer

Primary tumor (T)	Tis	Carcinoma in situ
	T1	Tumors ≤3 cm that do not invade the lobar bronchus and do not invade the visceral pleura
	T1a(mi)	Minimally invasive adenocarcinoma
	T1a	Tumors ≤1 cm
	T1b	Tumors >1 cm but ≤2 cm
	T1c	Tumors >2 cm but ≤3 cm
	T2	Tumors >3 cm but ≤5 cm *or* • Invades the visceral pleural • Invades the mainstem bronchus but not involving the carina • Is associated with atelectasis or obstructive pneumonia extending from the hilum
	T2a	Tumor >3 cm but ≤4 cm
	T2b	Tumor >4 cm but ≤5 cm
	T3	Tumors >5 cm but ≤7 cm *or* • Direct invasion of chest wall, phrenic nerve, mediastinal or parietal pleural, parietal pericardium • Superior sulcus tumors • Satellite tumor nodules within same lobe
	T4	Tumors >7 cm *or* • Invade any of the following: mediastinum, trachea, recurrent laryngeal nerve, carina, vertebral body, diaphragm, great vessels, or esophagus • Satellite tumor nodule within a different lobe of the ipsilateral lung
Regional lymph nodes (N)	N0	No regional lymph node metastases
	N1	Metastases or involvement by direct extension of ipsilateral peribronchial, intrapulmonary, or hilar nodes
	N2	Metastases to ipsilateral mediastinal or subcarinal lymph node
	N3	Metastases to any scalene or supraclavicular lymph node or to contralateral mediastinal or hilar nodes
Distant metastases (M)	M0	No distant metastases
	M1	Distant metastases present
	M1a	Satellite tumor nodule(s) in contralateral lung, pleural or pericardial nodules, or malignant pleural or pericardial effusion
	M1b	Single extrathoracic metastasis
	M1c	Multiple extrathoracic metastases in one or more organs

More than 75% of patients are symptomatic at the time of initial diagnosis due to the vast majority of lung cancer presenting at a later stage.[4,5] The National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) Program database survey of patients diagnosed with lung cancer demonstrates that the majority of patients continue to have either locally advanced (stage III) or metastatic disease (stage IV) at the time of diagnosis. Only ~25% of patients have

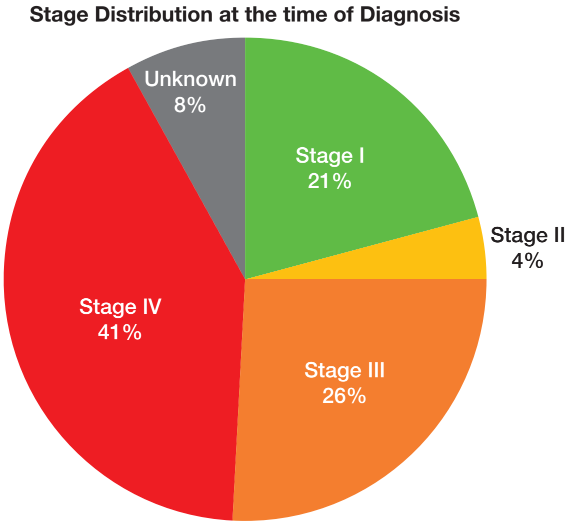

Figure 112-1 Stage distribution at the time of diagnosis.

stage I or stage II, whereas ~26% have stage III disease and ~41% have metastatic disease (stage IV) (Fig. 112-1).[6,7]

Patients often have had symptoms for months before diagnosis.[1,8,9] Symptoms, particularly those associated with localized disease such as cough, wheezing, and dyspnea, are often attributed to comorbid illnesses by both patients and their physicians. In one study in the United Kingdom of newly diagnosed lung cancer patients, symptom duration ranged from 4 to 24 months with a median of 12 months.[10] In one of the earliest series describing the relationship of presenting symptoms to stage and prognosis, about a third of patients (27%) presented with symptoms related to primary tumor only (Table 112-2), another third (34%) presented with nonspecific symptoms concerning for metastatic disease, and the final third (32%) presented with symptoms attributable to a distant metastatic site; only 6% were asymptomatic.[11]

Local symptoms can include cough, hemoptysis, dyspnea, chest pain, and wheezing.[12,13] Cough is the most frequently encountered presenting symptom and can be the result of endobronchial or parenchymal involvement by the primary tumor, regional lymph node enlargement, or postobstructive complications. Hemoptysis is the symptom that typically results in the most expeditious evaluation; about 5% of patients with hemoptysis and a normal chest x-ray will ultimately be diagnosed with lung cancer.[14] Chest discomfort and pain may indicate pleural involvement or direct tumor invasion of the chest wall or thoracic cage. Hoarseness, which can occur in up to 5% of lung cancer patients at presentation, suggests laryngeal nerve palsy, which can occur in 2% to 18% of lung cancer patients.[12] This is more commonly seen with left-sided tumors, which can involve the recurrent laryngeal nerve as it loops under the aortic arch.[13] Lung cancer accounts for up to 75% of all cases of superior vena cava (SVC) syndrome due to local compression or invasion.[15] Signs and symptoms of SVC syndrome include swelling of the face, neck, upper torso, and arms; and dyspnea. Up to 4% of patients with NSCLC and 10% of patients with SCLC develop SVC syndrome. Dysphagia suggests extrinsic compression of the esophagus due to bulky mediastinal disease, particularly involving the subcarinal lymph node, or it can result from direct esophageal invasion. Central tumors such as squamous cell carcinoma may cause airway obstruction resulting in a localized or unilateral wheeze, atelectasis, or postobstructive pneumonia.[16,17] Cancers arising in the lung apex (superior sulcus tumors) can present with Pancoast syndrome, an assortment of clinical manifestations due to invasion or compression of local structures.[18] Characteristic signs and symptoms include shoulder pain due to invasion of the brachial plexus and/or ribs and vertebrae, upper extremity weakness and paresthesia, and Horner syndrome (unilateral ptosis, miosis, and lack of facial sweating on the involved side) due to compression or invasion of the sympathetic chain.[18,19]

TABLE 112-2 Initial Signs and Symptoms of Lung Cancer

Signs and Symptoms	Range of Reported Frequencies (%)
Cough	8–75
Weight loss	0–68
Dyspnea	3–60
Chest pain	20–49
Hemoptysis	6–25
Bone pain	6–25
Fever	0–20
Weakness	0–10
Superior vena cava obstruction	0–4
Dysphagia	0–2
Wheezing	0–2

Focal symptoms of metastatic disease are fairly common at presentation: 25% of patients present with bone pain, 20% of patients present with symptoms associated with bulky mediastinal adenopathy such as cough and hoarseness, and 10% of patients have neurologic symptoms that may include headache, nausea and emesis, seizures, and/or mental status changes at the time of diagnosis.[12,13] Lung cancer accounts for approximately two-thirds of the cancers that first present as symptomatic brain metastases.[20] The presence of nonspecific constitutional symptoms (weakness, weight loss, fever, and anorexia) is worrisome for metastatic disease. Standard laboratory testing should include a complete blood count as well as chemistries that include liver function testing. Anemia (hematocrit <40% in men and <35% in women) may indicate a higher likelihood of metastatic disease. Similarly, elevated liver function tests are concerning for hepatic metastases.

Hooper et al.[21] have enumerated a standard set of clinical features found to be associated with metastatic disease (Table 112-3). A systematic review suggests that absence of all of these features makes metastatic disease highly unlikely with a negative predictive value exceeding 90%.[22,23]

Initial clinical evaluation of the patient with suspected lung cancer should also include an assessment for paraneoplastic syndromes (Table 112-4), clinical disorders associated with malignant disease that are not directly attributable to the physical effects of the tumor (Chapter 118). They may be seen in up to 10% of patients with lung cancer.[12] The most commonly recognized paraneoplastic syndromes are hormonally mediated; tumor cells secrete hormones or hormonal analogues. The syndrome of inappropriate antidiuretic hormone secretion (SIADH) is seen in 10% to 45% of patients with SCLC and 0.7% to 1% of patients with NSCLC (squamous cell and adenocarcinoma), although symptoms related to hyponatremia are present in just 1% to 5% of patients.[24,25] Hyponatremia is associated with decreased survival in SCLC.[26] Ectopic production of adrenocorticotropin hormone (ACTH) can be found in up to 50% of patients with

TABLE 112-3 Features of a Standardized Evaluation for Metastatic Disease

Symptoms	• Weight loss >10 lb • Focal skeletal pain • Neurologic symptoms: headaches, syncope, seizures, focal extremity weakness, altered mentation
Signs	• Palpable lymphadenopathy (>1 cm) • Hoarseness or SVC syndrome • Bone tenderness • Hepatomegaly (>13 cm) • Focal neurologic signs • Soft tissue mass
Laboratory testing	• Hematocrit <40% in men or <35% in women • Elevated alkaline phosphatase, liver function tests

TABLE 112-4 Paraneoplastic Syndromes Associated with Lung Cancer

System	Syndrome
Endocrine	SIADH Hypercalcemia Cushing syndrome Gynecomastia Hypercalcitoninemia Elevated LH and FSH Hyperthyroidism Carcinoid syndrome
Neurologic	Subacute sensory neuropathy Mononeuritis multiplex LEMS Encephalomyelitis Necrotizing myelopathy Cancer-associated retinopathy
Skeletal	Hypertrophic osteoarthropathy Clubbing
Renal	Glomerulonephritis Nephrotic syndrome
Metabolic	Lactic acidosis Hypouricemia
Systemic	Anorexia Fever
Rheumatologic	Dermatomyositis and polymyositis Vasculitis SLE
Cutaneous	Acquired hypertrichosis lanuginosa Erythema multiforme Tylosis Erythroderma Exfoliative dermatitis Acanthosis nigricans Sweet syndrome Pruritus and urticaria
Hematologic	Anemia Leukocytosis and eosinophilia Thrombocytosis Thrombocytopenia purpura Thrombophlebitis Disseminated intravascular coagulation

Data from Scagliotti G. Symptoms, signs and staging of lung cancer. Eur Respir Mon. 2001;17:86–119; Carbone PP, Frost JK, Feinstein AR, et al. Lung cancer: perspectives and prospects. Ann Intern Med. 1970;73:1003–1024.

lung cancer, but true Cushing syndrome is seen in only 1% to 5% of patients with SCLC.[12,24] Ectopic Cushing syndrome is also associated with a poor prognosis in SCLC, in part related to an increased susceptibility to opportunistic infection in patients given chemotherapy.[24,27–29] Hypercalcemia is seen in 2% to 6% of all lung cancer patients at presentation, and in up to 10% to 25% during their clinical course.[12,30] Etiology of hypercalcemia can be due to direct tumor effect on local osteolytic activity when there are bony metastases. However, in a substantial fraction of patients, typically those with squamous cell histopathology and less commonly in SCLC, hypercalcemia is due to tumor cell–elaborated parathyroid hormone–related peptide (PTHrP).

Digital clubbing and hypertrophic osteoarthropathy (HOA) are two paraneoplastic syndromes of the musculoskeletal system commonly associated with NSCLC (Chapter 27). Clubbing manifests as enlargement of the terminal tufts of the fingers and toes. It results from the proliferation of connective tissue beneath the nail matrix and can be seen in up to 29% of patients with adenocarcinoma or squamous cell carcinoma histopathology.[31] HOA, which occurs in fewer patients (<4%), presents as painful symmetric arthropathy, usually involving the ankles, wrists, and knees, and is caused by new periosteal bone formation at the distal long bones, resulting in vascular hyperplasia and edema. It is postulated that HOA occurs due to overexpression of vascular endothelial growth factor (VEGF).[32]

Other paraneoplastic syndromes associated with lung cancer occur due to the development of autoantibodies that can cause neurologic disease or rheumatologic disease. Dermatomyositis and polymyositis are autoimmune inflammatory myopathies characterized by progressive symmetrical proximal muscle weakness associated with various malignancies. Patients with dermatomyositis additionally may have Gottron papules and a heliotrope rash with poikiloderma. In two series, lung cancer accounted for 17.4% and 18%, respectively, of new cancer diagnoses within the first year of diagnosis of dermatomyositis.[33,34] The diagnosis can be confirmed by muscle or skin biopsy. Polymyositis is similarly associated with an increased risk of malignancy, with lung cancer accounting for 20% of newly diagnosed cancers during 5-year follow-up.[33]

There are a large number and variety of paraneoplastic neurologic syndromes (PNS) (Table 112-3).[35] Approximately 17% of paraneoplastic neurologic syndromes are due to lung cancer.[36] In 80% of cases, the neurologic disorder presents before the cancer is diagnosed; less than half will have detectable autoantibodies.[37] Although PNS are rare (<1% of all cancer patients), up to 3% to 5% of SCLC develop a PNS.[38] Lambert Eaton myasthenic syndrome (LEMS) is one of the better defined syndromes; it occurs due to the development of autoantibodies against presynaptic voltage-gated calcium channels. These circulating autoantibodies can be found in up to 5% to 8% of patients with SCLC although clinical LEMS occurs in only 1% to 3% of patients.[39,40] Other paraneoplastic neurologic syndromes occur due to the presence of circulating neuronal autoantibodies (including anti-Hu, anti-Yo, and anti-Ri antibodies) and have a myriad of clinical manifestations.[24] Up to 20% of patients with SCLC have circulating anti-Hu antibodies, although paraneoplastic syndromes do not occur in the majority.[41] The related syndromes can include autonomic overactivity, corticocerebellar degeneration, brainstem encephalitis, limbic encephalitis, myelopathy, and peripheral nerve palsies. Autopsy studies have revealed that patients suffering from these syndromes have lymphocytic inflammatory infiltration in areas of the nervous system corresponding to their neurologic deficits.

While paraneoplastic syndromes manifest systemically, they are not always indicative of advanced malignant disease. In one study, more than 40% of patients with SCLC-associated PNS had limited-stage disease at the time of diagnosis.[37] PNS may regress with appropriate treatment of the tumor.

IMAGING EVALUATION

Following the initial intake evaluation, further noninvasive and invasive workup should be undertaken with paired goals of (1) definitive establishment of histopathologic diagnosis and, when indicated, molecular and diagnostic biomarker testing, and (2) determination of disease stage in the most cost-effective and least invasive manner possible. Given the myriad of diagnostic modalities available, it is often advisable that patients suspected of having lung cancer undergo this phase of the evaluation at an established multidisciplinary lung cancer center.

Unless a patient is not a candidate for any treatment, all patients should undergo a chest computed tomography (CT) scan appropriately modified for lung cancer assessment. The lung cancer CT scan includes the chest and the upper abdomen such that the liver and the adrenal glands are visualized in their entirety. The administration of intravenous contrast facilitates better characterization of hilar and mediastinal lymph nodes by differentiating them from vascular structures and also helps to better characterize hepatic and adrenal lesions. CT is most useful in delineating the key features of the primary tumor (size, presence of satellite nodules, associated atelectasis and infection, and invasion of adjacent structures); these features are essential in establishing the clinical T stage (Chapter 28).

Regional lymph node involvement can also be evaluated on chest CT. Lymph nodes are deemed to be pathologically enlarged when they measure greater than 1 cm in short-axis diameter on transverse images. The likelihood of metastatic involvement increases with the degree of lymph node enlargement: 62% of lymph nodes measuring 10 to 15 mm are malignant versus 90% of nodes measuring >15 mm.[42] However, in most patients, lymph node staging cannot be accurately undertaken based upon CT findings alone. In a meta-analysis of 35 studies (5111 patients, 28% of whom had mediastinal metastases), the pooled sensitivity of CT scanning for mediastinal nodal metastases was found to be 51% and pooled specificity, 86%.[43] About 20% of nodes deemed to be benign on chest CT were malignant and 40% of nodes deemed abnormal on chest CT were benign.

On occasion, there are CT findings that demonstrate mediastinal tumor invasion convincingly enough that further staging is unnecessary. These findings include extensive infiltration of mediastinal structures such that discrete anatomic landmarks are lost, matting of nodal tissue such that boundaries become indistinct, and encircling of mediastinal structures by infiltrating tumor. In the absence of these findings, further studies need to be undertaken to adequately stage the mediastinum.

Chest CT scan can also often demonstrate findings that may be suggestive of metastatic disease. CT may delineate pleural effusions, the majority of which are malignant. Also, CT may reveal pericardial effusion, pleural nodularity, or nodules in the contralateral lung, all of which may indicate metastatic disease. Bony involvement of the thoracic cage may be seen. Adrenal lesions can be identified in 4% to 18% of patients; however, up to 50% of these are ultimately found to be benign.[44]

Positron emission tomography (PET) with 18-fluoro-2-deoxyglucose (FDG) has a prominent role in the initial noninvasive evaluation of the patient with suspected lung cancer.[45] Metabolically active tissues avidly take up the glucose analogue FDG and appear bright on PET scan. Strongly hypermetabolic activity raises suspicion of malignancy. However, hypermetabolic activity can also be seen in inflammatory processes related to infections, sarcoid, vasculitis, recent surgery, or reaction to immunotherapy, limiting the specificity of PET to ~85%.[46] False negatives can also occur with low-grade malignancies or small foci of malignancy, leading to a sensitivity of 96%.[46] Lesions less than 0.8 to 1.0 cm may be too small for accurate assessment.[47] High-level physiologic uptake within the brain, heart, gastrointestinal, and genitourinary tracts may compromise precise evaluation of tumor invasion or metastasis in these areas. In addition, the presence of hyperglycemia can interfere with the uptake of FDG and thus increase the likelihood of false-negative examinations.[48] The PET scan is more sensitive and specific than CT in regional lymph node assessment with a pooled sensitivity of 74% and specificity of 85% in the identification of mediastinal lymph node metastases.[45] In patients with enlarged mediastinal nodes, the sensitivity has been estimated to be as high as 100% with a specificity of 78%.[46] Thus the false-positive rate ranges between 13% and 25% in patients with nodal enlargement. In those with normal-sized nodes on CT, PET sensitivity is 82% but specificity is higher at 93%. Approximately 20% of patients with normal mediastinal nodes on CT and PET will have malignant disease within the mediastinum.[46]

PET scanning can disclose unsuspected metastatic disease (M1) in 6% to 37% of cases, depending on clinical pretest probability. Rates are lower in earlier-stage disease: 1% to 8% in clinical stage I disease and 7% to 18% in patients with clinical stage II disease.[45] Liver metastases, adrenal metastases, and bone metastases can be diagnosed with good accuracy. A recent study of PET-CT in the evaluation of adrenal lesions detected in patients with lung cancers reported an overall sensitivity and specificity of 97% and 94%, respectively.[49] Two systematic reviews suggest that PET scanning has a higher diagnostic value than bone scintigraphy for the detection of bone metastases from lung cancer, with >90% sensitivity and specificity for PET-CT.[50,51]

PET-CT has been the most helpful in decreasing the frequency of understaging in patients at risk for advanced lung cancer. Clinical trials have suggested that the addition of PET-CT imaging to the evaluation results in a reduction of the rates of noncurative surgery for NSCLC from 40% down to 20%.[52–54] The frequency of understaging disease decreases from 30% to 15%. The beneficial impact of PET diminishes in a patient with early-stage disease. PET correctly detects N2, N3, or M1 disease in 7% to 10% of patients with clinical stage I disease.[55] However, this comes at a cost of increased false-positive rate of up to 14%. PET should not be used alone to confirm advanced-stage disease as patients may be erroneously directed away from curative therapies.

MRI scanning is the test of choice when assessing for intracranial metastatic disease. It is more sensitive than a CT scan of the brain.[56] Staging brain MRI should be considered in patients who present with locally advanced or advanced NSCLC on chest CT or PET scanning (clinical stage IB through IV); patients with neurologic signs or symptoms; patients presenting with nonspecific constitutional symptoms of fevers, weight loss, anorexia, and weakness; and all patients with SCLC.[57–59] MRI scanning is also often the test of choice for focused examination for the extent of chest wall invasion, diaphragmatic involvement, superior sulcus tumors, brachial plexus invasion, or invasion of the spine (TNM T4 disease).[60]

Any extrathoracic lesion detected on imaging studies in a patient suspected of having lung cancer should be biopsied first, if feasible.

This will accomplish not only tissue diagnosis but also confirmation of advanced disease in both SCLC and NSCLC.

ESTABLISHING THE TISSUE DIAGNOSIS

Methods employed in establishing a tissue diagnosis SCLC and NSCLC are discussed below.

■ Small-cell Lung Cancer

Specific imaging characteristics on chest CT can be indicative of SCLC. In particular, the findings of massive lymphadenopathy, direct mediastinal invasion, or hilar masses can suggest SCLC. The suspicion should be raised if the clinical evaluation is worrisome for SIADH, ectopic ACTH production, or PNS. If SCLC is suspected, then tissue diagnosis should be established utilizing the least invasive test feasible.

In 1989, the International Association for the Study of Lung Cancer (IASLC) modified the Veterans Administration Lung Study Group (VALSG) two-stage classification of SCLC; this modified classification system is currently the widely accepted clinical staging system for SCLC.[61] Patients with limited-stage disease have disease confined to one hemithorax, the mediastinum, and ipsilateral supraclavicular lymph nodes. In other words, limited-stage defines a primary tumor and regional nodes that can be incorporated into a reasonably safe radiation port. Patients with extensive-stage disease have malignant pleural and pericardial effusions, contralateral hilar or supraclavicular nodes, and/or distant metastases. Given the high likelihood of extensive disease at the time of presentation, all patients should undergo a full staging evaluation that traditionally included a contrast-enhanced CT of the chest and abdomen, bone scan, and MRI or contrast-enhanced CT scan of the brain. MRI scanning, the preferred imaging modality, will detect brain metastasis in 10% to 15% of asymptomatic patients with SCLC at the time of diagnosis, and in 12% of patients with otherwise limited-stage SCLC.[40,62] Routine bone marrow aspiration is not indicated. The use of PET scan in the initial staging of SCLC has been evaluated in several small studies.[50–54,63–67] Because SCLC is a highly metabolic malignancy, PET scan is 100% sensitive for the detection of the primary tumor. Also, PET is superior to standard imaging in both sensitivity and specificity for detection of non-CNS metastatic foci. In a systematic review, PET/CT changed binary SCLC staging in 15% of patients.[68] In patients with radiographic evidence of extensive-stage SCLC, tissue diagnosis and stage confirmation should be accomplished by biopsy of a metastatic focus if feasible.

■ Non–small-cell Lung Cancer

In the case of NSCLC, the primary goals in tissue sampling selection are more complicated. These goals are (1) to obtain a tissue specimen adequate for histopathologic subtyping, molecular biomarker testing to identify actionable mutations, and diagnostic biomarker testing (PD-L1 expression), and (2) to establish the clinical stage of disease in the least invasive manner feasible. If imaging tests suggest a site of distant metastatic disease, then that site should be sampled first, if accessible.

Sputum cytology is the least invasive way of achieving a histologic diagnosis. However, it is also the least accurate and least useful for therapeutic analysis. For these reasons, it has largely been replaced by other methods and is generally of historic interest only. Thoracentesis is indicated as the initial test for tissue acquisition when a pleural effusion is present in a patient suspected of having lung cancer. Malignant pleural effusion (MPE) is common at the time of presentation—11% and 16% to 26% in patients with SCLC and NSCLC, respectively.[69,70] Additionally, up to 40% will develop a MPE during the disease.[71] Positive pleural fluid cytology not only establishes the diagnosis but also establishes stage IV (M1a) disease in NSCLC and extensive-stage SCLC. Due to the decrease in complications, improvement in procedure success rates associated with ultrasound guidance, and ubiquitous nature of ultrasound equipment, ultrasound-guided thoracentesis is the standard of care.[72,73] Furthermore, ultrasound imaging can reveal findings that raise the suspicion for malignant disease, including pleural thickening and nodularity.[74] Pleural fluid cytology sensitivity for malignancy overall is approximately 60% to 72% when a volume of at least 50 mL is sent; diagnostic yield does not appear to increase with larger volume of fluid analyzed.[75–77] If the initial thoracentesis is negative, a second thoracentesis should be performed, as it can increase the diagnostic yield by an additional 27%; additional samples add little to the diagnostic yield.[78] Sensitivity of pleural fluid cytology can be as high as 72% when at least two separate specimens are sent.[79]

When pleural disease is present and thoracentesis is negative, additional diagnostic strategies include non-image-guided closed pleural biopsy, percutaneous image-guided biopsy, and thoracoscopic biopsy. Non-image-guided closed pleural biopsy using an Abrams needle is uncommonly employed as it increases diagnostic yield over thoracentesis by only 7% to 27%.[79] Percutaneous image-guided pleural biopsy has clear advantages in diagnostic yield, particularly when there are abnormal pleural findings on ultrasound or chest CT, with a sensitivity of 84%.[79] Thoracoscopy has a reported sensitivity of 80% to 99% in the diagnosis of malignant pleural disease.[79] However, when there is CT evidence of pleural thickening or nodules, the diagnostic yield of image-guided percutaneous biopsy is similar to thoracoscopy. Thus, medical or surgical thoracoscopy should be reserved for patients with pleural fluid but without a discrete target for image-guided pleural biopsy.[80]

HISTOLOGIC SAMPLING OF THE PRIMARY TUMOR

There are numerous procedures presently utilized to sample the primary tumor with varying diagnostic yields depending on tumor characteristics and adjunct technologies (Table 112-5). Bronchoscopy enables sampling of the primary tumor as well as the mediastinum for regional lymph node staging (Chapters 33 and 34). The overall sensitivity of endobronchial forceps biopsy of directly visualized central tumor is 74%, with yield increasing with the number of biopsy passes.[79] It is recommended that at least three biopsies be taken. The yield of endobronchial washes and brushes is lower (sensitivity 47% and 61%, respectively) but may have additive benefit.[79] Endobronchial needle aspiration further increases yield, as forceps biopsies of endobronchial lesions can sometimes sample areas of necrosis and may result in nondiagnostic biopsies.[81–83] When all techniques are utilized, the reported yield of bronchoscopic sampling of endobronchial lesions can be as high as 91% to 96%. Bronchoscopic visualization of endobronchial disease is also the best way to estimate the extent of proximal tumor invasion, aiding in differentiating the T stage of centrally located tumors. Specifically, if the tumor invades the mainstem bronchus but spares the carina, it is a T2 lesion while involvement of the carina or trachea designates a T4 lesion.

Advanced bronchoscopic techniques such as electromagnetic navigational (EMN) bronchoscopy and radial probe endobronchial ultrasound (R-EBUS) have improved the diagnostic armamentarium for peripheral lung cancers. R-EBUS permits direct real-time ultrasound imaging of target lesions; early studies suggested R-EBUS can increase the overall sensitivity of bronchoscopic biopsy of peripheral lesions up to 73%.[84] EMN bronchoscopic technology creates a real-time virtual thoracic map that helps the bronchoscopist steer electromagnetically tracked tools through subsegmental airways toward the target lesion, with initial reports and subsequent meta-analysis suggesting that EMN increases the diagnostic yield of bronchoscopic biopsy of peripheral lesions from 57% overall to 70%.[85] Despite the early reports of diagnostic

TABLE 112-5 Sampling of Primary Tumor

Tumor Characteristics	Procedure	Sensitivity (%)	Comments
Directly visualized endobronchial tumor	Bronchoscopy with forceps biopsy	74	
	Bronchoscopic washes	47	
	Endobronchial brush	61	
	Needle aspiration	75–96	
Peripheral lesions	Transbronchial biopsy		Yield increases with number of biopsy passes: 45% for one sample and 70% for six samples[75]
	Overall	57	
	Lesions <2 cm	34	
	Lesions >2 cm	63	
	Transbronchial brush	54	
	Bronchoalveolar lavage/wash	43	
	Transbronchial needle aspiration	65	
	Combination of all modalities	78	
	Radial EBUS	50–57	Yield increases with "bronchus sign"—subsegmental bronchus leading to lesion on chest CT[96,97]
	Overall	31	
	Lesions ≤2 cm	58	
	Lesions >2 cm		
	EMN bronchoscopy	50–57	
	Transthoracic needle aspiration	90	Pneumothorax rate 20%
	CT guided	92	Core biopsy similar to FNA for malignancy but better to determine benign diagnoses[99]
	Fluoroscopically guided	88	

yields and sensitivity greater than 70%, more recent, large, multicenter registries and prospective randomized trials suggest guided bronchoscopy (R-EBUS, EMN, or both) results in an overall yield for peripheral lesion biopsy of 50% to 57%.[86–88] Some factors that increase the yield and sensitivity of guided bronchoscopy are as follows: (1) when CT scanning demonstrates that a subsegmental bronchus leads directly into the lesion (bronchus sign), yield increases up to threefold;[85,89] and (2) the addition of needle aspiration has been suggested to improve the yield up to twofold.[86,90,91] Lesion size, as with fluoroscopically guided procedures, continues to influence test performance, with a diagnostic yield between 50% and 67% for lesions less than or equal to 2.0 cm, increasing to 71% to 79% for larger lesions.[86] Procedural complications are minimal, with an overall rate of pneumothorax of 1% and pneumothorax requiring catheter drainage of 0.4%.[85]

Image-guided transthoracic needle biopsy (TTNB) has excellent sensitivity for peripheral lesions, with a pooled sensitivity of approximately 90%.[79] However, a negative biopsy does not rule out malignant disease. The false-negative rate can range between 20% and 30% depending on patient population and disease characteristics.[79] CT guidance is superior to fluoroscopic guidance. The addition of transthoracic core biopsy has a sensitivity equivalent to fine-needle aspiration biopsy (FNAB) but increases the ability to establish a specific histopathologic diagnosis by improving tissue acquisition for immunohistochemical staining and molecular characterization in up to 98% of cases. In addition, a core biopsy improves the diagnostic yield of specific benign etiologies from 52% with FNAB to 91%.[92] The complication rate of TTNB is higher than that associated with bronchoscopy. The incidence of pneumothorax is ∼20% and the incidence of severe hemorrhage is 1%.[93] Risk factors for complications include underlying chronic obstructive pulmonary disease, small lesion size, long needle path, repeated pleural puncture, and proximity to pleural fissures and diaphragm.[94] In addition to the higher complication rate associated with TTNB compared to bronchoscopy, TTNB cannot provide mediastinal staging. Therefore, TTNB is recommended as the first line for biopsy of peripheral lung lesions in intermediate to high lung cancer likelihood patients when (1) the lesion is peripheral; (2) the lesion is less than 3 cm in size; (3) there is no CT/PET evidence of mediastinal lymph node or extrathoracic metastasis; and/or (4) the patient is a poor surgical candidate.[79]

Video-assisted thoracoscopic surgery (VATS) wedge resection followed by definitive anatomic resection (e.g., lobectomy) as indicated is the gold standard for peripheral lung biopsy with the highest sensitivity and specificity (Chapter 35). Because of the invasive nature of the procedure, it requires hospitalization and carries a higher attendant risk. It can be combined with bronchoscopic mediastinal staging or mediastinoscopy; however, as described in the next section, bronchoscopic mediastinal staging is less invasive, more cost-effective, and equally sensitive and specific for mediastinal staging. Furthermore, unnecessary surgery can be avoided in 29% to 66% of patients presenting with clinical early-stage lung cancer who undergo mediastinal lymph node staging.[95–97] Therefore, in patients who have an acceptable surgical risk profile, a peripheral lesion less than 3 cm, and no CT/PET evidence of metastatic disease (lymph node or extrathoracic), definitive VATS resection is preferred, as it provides both diagnosis and cure in one procedure.[45,98] Otherwise, despite overall lower yield, bronchoscopic sampling has become the preferred biopsy method in centers where advanced bronchoscopy technologies, including R-EBUS and EMN, are available for the following situations: (1) when combined with mediastinal staging in patients with central lesions, peripheral lesions at least 3 cm, and/or CT/PET evidence of mediastinal lymphadenopathy; (2) in low-intermediate or indeterminate cancer likelihood patients to establish a nonmalignant diagnosis; (3) in poor surgical candidates with lesions greater than 2 cm being considered for stereotactic body radiation (SBRT) as fiducials can be placed at the time of biopsy.[79]

TABLE 112-6 Classification of Mediastinal Disease by Radiographic Characteristics

Group	Description
A	Mediastinal infiltration: tumor invasion such that normal anatomic boundaries cannot be distinguished
B	Enlarged discrete mediastinal lymph nodes: lymph nodes measuring ≥1 cm in short-axis diameter on transverse CT scan
C	Clinical stage II or central stage I tumor: normal-sized mediastinal lymph nodes but enlarged N1 nodes or central tumor
D	Peripheral clinical stage I tumor: normal mediastinal and hilar nodes with a peripheral tumor

Adapted with permission from Detterbeck FC, Jantz MA, Wallace M, Vet al. Invasive mediastinal staging of lung cancer: ACCP evidence-based clinical practice guidelines (2nd edition). Chest. 2007;132(3 Suppl):202S–220S.

MEDIASTINAL STAGING

Lung cancer staging is based upon the tumor node metastasis (TNM) staging system last updated on January 1, 2018 (Table 112-1) by the International Association for the Study of Lung Cancer. Extent of disease is categorized by the characteristics of the primary tumor (T), the involvement of regional lymph nodes (N), and the presence or absence of distant metastases (M).[3] Disease stage is the key determinant of candidacy for tumor resection. Patients with stage I and II diseases and otherwise adequate cardiopulmonary reserve should undergo surgery. Unfortunately, only about one-third of patients present as stage I or II and therefore would benefit from surgery after thorough clinical staging.[7,99,100]

Nearly a quarter of patients with lung cancer have locally advanced disease with mediastinal involvement (N2 or N3) at the time of presentation.[4,6] Mediastinal staging is crucial in determining the stage of disease and candidacy for surgical resection once metastatic disease has been ruled out, as 29% to 66% of noncurative surgeries for lung cancer can be avoided with adequate mediastinal staging.[95–97] Tissue confirmation of mediastinal nodal metastasis becomes unnecessary only in the following situations: (1) where distant metastatic disease has already been confirmed; (2) when the patient is not a candidate for any treatment; (3) in a peripheral lesion, less than 3 cm in size, with no radiographic evidence of lymph node metastasis.

Patients with NSCLC fall into four categories concerning the approach to clinical staging of the mediastinum based on the radiographic findings (Table 112-6).[96] Radiographic group A includes patients who have imaging characteristics that are unequivocally consistent with malignant invasion of the mediastinum (mediastinal infiltration with loss of normal tissue boundaries, nodal tissue is no longer discrete and can be matted together, and vascular structures are often encircled) (Fig. 112-2). In this group of patients, the goal is

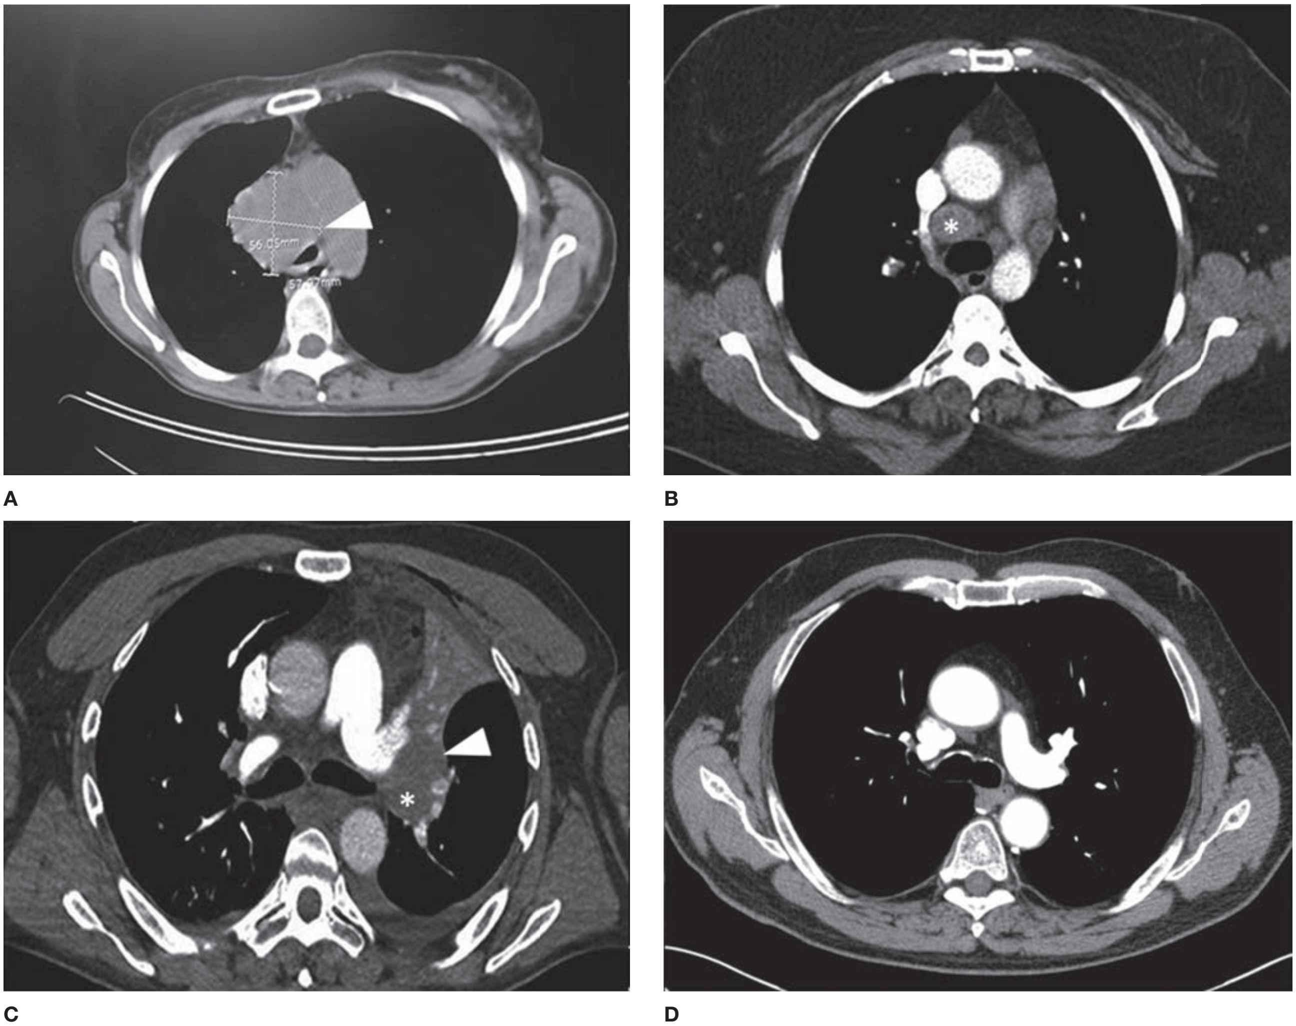

Figure 112-2 Example of radiographic group A disease: mediastinal infiltration with loss of normal anatomic boundaries.

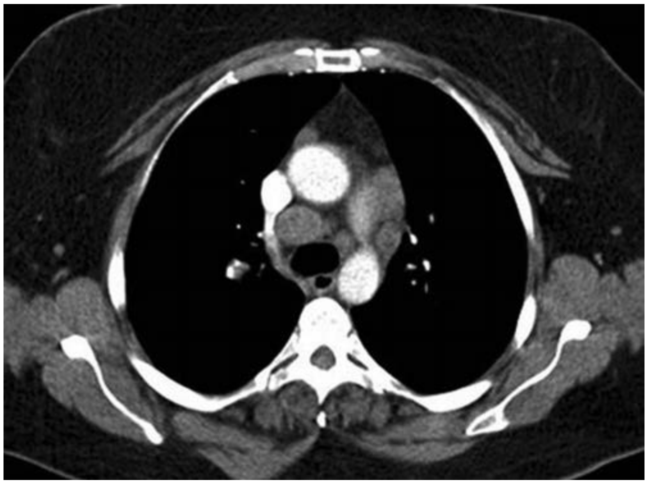

Figure 112-3 Example of radiographic group B disease: discrete mediastinal (4R) nodal enlargement.

to obtain tissue by the least invasive procedure to establish the diagnosis. Group B includes patients with discrete lymph node enlargement (Fig. 112-3). Discrete enlargement of lymph nodes on a CT scan, even massive enlargement, is inadequate evidence for mediastinal metastases as up to 40% of these nodes are benign.[43] Conversely, group C includes patients with central lesions or N1 disease with radiographically normal mediastinal lymph nodes (Fig. 112-4). In this group, 20% to 25% are found to have nodal involvement.[43] Finally, the last group of patients, group D, includes those with peripheral clinical stage I lesions with radiographically normal mediastinal and hilar lymph nodes. These patients have a sufficiently low pretest probability for mediastinal involvement that invasive mediastinal sampling becomes unnecessary. In patients with radiographic group B or C disease, adequate staging of the mediastinum is mandatory.

Mediastinal staging procedures include transthoracic needle aspiration (TTNA), transbronchial needle aspiration (TBNA) with or without EBUS, endoscopic ultrasound (EUS) needle aspiration, cervical mediastinoscopy, anterior mediastinoscopy, and thoracoscopy. Selection of appropriate procedure is made based upon nodal station (Table 112-7), the pretest probability of disease, and medical appropriateness for surgical resection.[96] The diagnostic yield of each procedure (Table 112-8) should also be taken into account.

TTNA of mediastinal nodal tissue is possible when anterior mediastinal lymph nodes (anatomic stations 3a and 6) are enlarged. A recent systematic review reported a pooled sensitivity of 94%.[45] As with TTNA of peripheral lesions, the risk of pneumothorax is fairly high. Chest tubes are required for evacuation of pneumothorax in 10% of procedures.[96] TTNA of the mediastinum is primarily utilized in patients with fairly bulky anterior mediastinal lymph node enlargement.

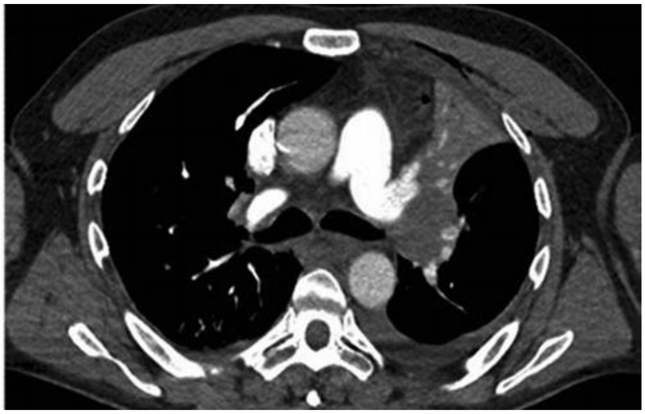

Figure 112-4 Example of radiographic group C disease: central lesion with N1 disease but no enlarged mediastinal lymphadenopathy.

TABLE 112-7 Regional Lymph Node Stations (International Association for the Study of Lung Cancer)

Zone	Lymph Node Station	
Supraclavicular zone	1	Low cervical, supraclavicular, sternal notch
Superior mediastinal nodes	2R	Right upper paratracheal
	2L	Left upper paratracheal
	3a	Anterior mediastinum—prevascular
	3p	Posterior mediastinum—retrotracheal
	4R	Right lower paratracheal
	4L	Left lower paratracheal
Aortic nodes/aortopulmonary window nodes	5	Subaortic
	6	Para-aortic
Inferior mediastinal nodes	7	Subcarinal
	8	Paraesophageal nodes
	9	Pulmonary ligament
Hilar nodes	10	Hilar nodes
	11	Interlobar nodes
Peripheral nodes	12	Lobar nodes
	13	Segmental nodes
	14	Subsegmental nodes

Data from Rusch VW, Asamura H, Watanabe H, Giroux DJ, Rami-Porta R, Goldstraw P. The IASLC lung cancer staging project: a proposal for a new international lymph node map in the forthcoming seventh edition of the TNM classification for lung cancer. Journal of Thoracic Oncology. 2009;4(5):568–577.

Bronchoscopic sampling of mediastinal lymph nodes with TBNA without image guidance can potentially access stations 2, 4, 7, 10, and 11 with variable yield.[101] The availability of rapid on-site cytologic evaluation improves diagnostic yield and decreases the number of biopsy passes needed.[102] However, the widespread adoption of convex probe EBUS (CP-EBUS) to guide TBNA has largely supplanted "blind" sampling. The advent of CP-EBUS has significantly improved the diagnostic yield of TBNA sampling of the mediastinum. EBUS allows for real-time visualization of the target nodal tissue with a pooled sensitivity on a systematic review of 87% compared to 86% with video-assisted mediastinoscopy. It is now recommended as the first procedure, if available, for sampling the hilar and mediastinal nodes.[45,103] EBUS-TBNA provides access to nearly all lymph node stations (2, 4, 7, 10, and 11), combines diagnosis and staging in a single procedure, and results in equivalent diagnostic yield when compared with mediastinoscopy.[104–106] Performance is best in patients with positive CT or PET results, with a sensitivity of 94% in that population, for whom the false-negative PET rate remains substantial at 24%.[105] Evaluation of tissue adequacy for immunohistochemical testing and molecular characterization suggests that EBUS-TBNA can result in satisfactory sampling for both tumor subtyping and molecular markers in >94% of cases.[107] When assessed for adequacy for immunohistochemical subtyping, next-generation genetic sequencing,

TABLE 112-8 Mediastinal Staging

Procedure	Lymph Node Stations	Sensitivity (%)	Comments
TBNA	4, 7, and 10	78	
EBUS-TBNA	2, 4, 7, and 10	88–93	Sensitivity 94% in PET positive lymph nodes.
EUS-FNA	5, 7–9	83, overall 90, enlarged nodes 58, normal-sized nodes	
CT-guided TTNA	3a, 5, 6	92	Requires bulky disease in 5–6.
Mediastinoscopy	1, 2R, 2L, 3, 4R, 4L, anterior subcarinal (7)	81	
Thoracoscopy	4, 7–10	99	Typically, only one side of the mediastinum is sampled. Right side is more easily accessible than the left.

and ALK molecular testing, EBUS-TBNA was sufficient in 82% of 112 patients in one study, and 90.6% of 85 patients in another.[108,109] Diagnostic yield and sample adequacy are related to the expertise of the bronchoscopist and cytopathologist, respectively, and there is significant heterogeneity in yield across hospitals.[110] Therefore, negative sampling in patients with high pretest probability for lymph node metastasis should be followed by mediastinoscopy in patients who are candidates for surgical resection.[45]

EUS fine-needle aspiration (EUS-FNA) can access the inferior mediastinal nodal stations as well as nodal tissue in the subaortic stations: 9, 8, 7, and 5. Like bronchoscopy, EUS-FNA is minimally invasive and is an outpatient procedure. In addition, the left adrenal gland, celiac lymph nodes, and lesions involving the left lobe of the liver can be sampled utilizing this technique. The sensitivity for accessible mediastinal lymph nodes is excellent at 83% with an overall false-negative rate of 19%.[111] Yield is highest with enlarged nodes with a sensitivity of 90% and a false-negative rate of 22%.[111] In the hands of expert endoscopists, normal-sized nodes may also be sampled with a reported sensitivity of 58% for metastatic disease.[111] While a negative test impels further testing, a positive study obviates the need for more invasive evaluation.

When EUS is combined with EBUS, the mediastinum can be more extensively sampled than with either modality alone. In the studies investigating this combined approach, sensitivity ranged between 72% and 100% with 98% to 100% specificity.[112–118] Negative predictive values ranged between 80% and 100%. This combined approach requires highly specialized expertise and is available only at selected centers.

Cervical mediastinoscopy is typically a same-day surgical procedure in which an incision is made just above the suprasternal notch and a mediastinoscope inserted. It is a low-morbidity procedure with complication rates of 2% and mortality of 0.08%.[96] The high and low paratracheal nodes (2R, 2L, 4R, and 4L), pretracheal (1 and 3), and anterior subcarinal (7) nodal stations can be sampled. Mediastinoscopy is the procedure of choice to demonstrate node negativity before surgical resection of the primary tumor in cases where FDG avid mediastinal nodes are found to be negative for malignancy on EBUS-TBNA staging. Test sensitivity has been reported to be overall 80% with a false-negative rate as high as 10%.[96] The lymph nodes identified as false negatives are often located in nodal stations not accessible to the mediastinoscope. The addition of video mediastinoscopy may further improve test performance with sensitivity increasing to 80%.[96] A Chamberlain procedure (i.e., anterior mediastinoscopy) can be performed to sample aortopulmonary and anterior mediastinal nodal stations (stations 5 and 6), commonly involved with left upper lobe cancers that are not accessible by EBUS-TBNA, to rule out N2 disease.

VATS can be utilized to sample multiple lymph node stations, including the right paratracheal (station 4R) nodes, stations 5 and 6 nodes, paraesophageal nodes, and stations 9 and 10 nodes, and is guideline-directed care at the time of curative intent surgery for clinical/radiographic stage I or II NSCLC when there are no enlarged lymph nodes on CT and there is no FDG uptake in lymph nodes on PET/CT.[98] The left paratracheal lymph nodes are much more difficult to access. VATS sampling also provides the most reliable information short of full thoracotomy regarding the extent of primary tumor invasion of the chest wall and mediastinal structures as well as pleural and pericardial involvement.

TISSUE ACQUISITION FOR HISTOPATHOLOGY AND MOLECULAR AND DIAGNOSTIC BIOMARKER TESTING

NSCLC encompasses a heterogeneous group of cancers with not just different histologies but also different genetics. In addition, NSCLCs respond differently to therapeutic agents depending on histology and molecular characteristics. Significant positive outcomes have been reported when certain adenocarcinomas are combined with specific chemotherapy agents (e.g., pemetrexed) and tyrosine-kinase inhibitors (e.g., erlotinib), while patients with squamous cell histology are clearly at higher risk of toxicity from bevacizumab.[119,120]

Molecular translational research has resulted in identification of genetic alterations in oncogenes and tumor suppressor genes critical to tumor growth, leading to significant improvements in treatment of metastatic NSCLC, as these somatic mutations are clinically actionable with targeted agents. Oncogenic mutations are detected in roughly 64% of NSCLC and include mutations in the epidermal growth factor receptor (*EGFR*), rearrangements of the anaplastic lymphoma kinase (*ALK*) gene or c-ROS oncogene 1 (*ROS1*) gene, mutations in human epidermal growth factor receptor 2 (*HER2*), high-level MET amplification, and *MET* exon 14 and *RET* gene rearrangements.[121–125] Targeting with a specific therapy has, in some cases, resulted in dramatic response rates and improvement in survival compared with cytotoxic chemotherapy.[126] In addition to targeted therapies, inhibition of immune checkpoints has shown promise and has become integrated into the clinical management of metastatic NSCLC.[127] Immunotherapy results in superior survival with less toxicity compared with cytotoxic chemotherapy in patients with a high level of PD-L1 expression, with estimated 5-year overall survival rates of 23.2% and 15.5% in treatment-naïve and in previously treated patients, respectively.[128]

Guidelines recommend routine molecular biomarker testing (*EGFR*, *ALK*, *ROS-1*, *BRAF*, *HER2*, *MET*, *RET*, and *KRAS*) in all patients with advanced-stage adenocarcinoma, large cell carcinoma, and NSCLC otherwise not specified, and in select patients with squamous NSCLC.[129,130] Testing for molecular biomarkers should ideally be done in laboratories that perform next-generation sequencing panels.[130] Guidelines also recommend that diagnostic biomarker testing (PD-L1 expression) be performed in all patients with advanced-stage NSCLC.[129]

The emergence of individually tailored therapy based on histology and molecular and diagnostic biomarkers serves to emphasize how important adequate tissue acquisition is when diagnosing lung cancer. It has become incumbent upon clinicians who perform diagnostic studies to obtain sufficient tissue to perform immunohistochemical and molecular analysis to accurately ascertain the histologic subtype and molecular characterization of NSCLC. The impetus to obtain larger pieces of tissue can often seem discordant with the other objective of tissue acquisition, which is to achieve diagnosis and staging in the least invasive manner possible. In an era of minimally invasive procedures, several studies have reported high feasibility (range, 67%–100%) of performing immunohistochemical staining and molecular analysis and PD-L1 testing on specimens obtained via EBUS-TBNA.[131–135] Given the excellent performance of smear preparations, guidelines support performing molecular and diagnostic biomarker testing on any cytology sample with adequate cellularity and preservation.[136] Preservation of material from needle aspirates in cell block can store tumor cells for future immunohistochemical and molecular studies. How much tissue is needed to accurately diagnose the lung cancer histologic type and assess molecular markers has not been formally studied. It has been reported that one aspiration per lymph node station during EBUS-TBNA without rapid on-site cytology results in sample adequacy of 90% compared with 100% for three aspirations.[137]

SUMMARY

- Initial clinical evaluation of a patient with suspected lung cancer should focus upon presenting symptomatology as well as signs and symptoms suggestive of advanced-stage disease. History and laboratory testing may also be revealing for paraneoplastic syndromes.
- Initial imaging evaluation should include a chest CT scan for all patients who may be candidates for treatment. Integrated PET-CT scanning is indicated for the majority of patients, particularly for those who are at risk for mediastinal involvement as well as those patients with advanced thoracic disease and thus are at risk for distant metastatic disease. CT with contrast or MRI of the brain should be performed to assess for intracranial metastases in patients with neurologic symptoms or to screen for intracranial metastases in patients with locally advanced or advanced NSCLC, and those with SCLC.
- When SCLC is suspected, tissue diagnosis should be obtained in the least invasive manner possible. Staging classification is either limited-stage or extensive-stage disease and if feasible, a suspicious metastatic lesion should be biopsied first to confirm diagnosis and stage. In selected cases, staging can be accomplished through imaging evaluation alone (e.g., patient with multiple brain lesions or multiple bone lesions).
- Multiple diagnostic modalities are available to establish tissue diagnosis and to confirm the clinical stage. Selection should be based upon diagnostic yield, procedure safety, and ability to simultaneously establish stage. Thus, priority should be given to procedures that sample foci of metastatic disease detected on imaging evaluation (e.g., thoracentesis when pleural effusions are present, biopsy of PET-CT avid adrenal, bone, or hepatic lesions).
- Tissue sampling from the primary tumor can be accomplished percutaneously, bronchoscopically, and surgically. Yield of bronchoscopic biopsy for peripheral lung lesions is still not as high as that seen with TTNA. However, the advent of new techniques such as R-EBUS and EMN has improved test performance. Bronchoscopy remains the procedure with the lowest complication rate and should be strongly recommended as the procedure of choice in centers with local expertise.
- EBUS-TBNA is the procedure of choice for sampling hilar and mediastinal lymph nodes.
- In the absence of M1 disease, clinical staging of the mediastinum becomes crucial unless the patients have radiographic findings of mediastinal invasion or the patient has a sufficiently low pretest probability of mediastinal metastasis (peripheral T1N0 lesion). Ultrasound-guided bronchoscopic and endoscopic techniques have resulted in much improved diagnostic yield with excellent procedural safety. However, negative results should prompt surgical mediastinal sampling.
- The emergence of targeted therapies and immunotherapy has resulted in a greater emphasis on adequate tissue acquisition for molecular and diagnostic biomarker analysis.

CHAPTER 113

Treatment of Non–Small-Cell Lung Cancer: Surgery

John K. Waters
Scott I. Reznik

INTRODUCTION

Lung cancer is the deadliest malignancy, accounting for more annual deaths than breast, prostate, and colorectal cancer combined. In 2018, 1.7 million people died worldwide from this disease, which accounts for 18.4% of all cancer deaths.[1] In 2020, it will claim the lives of 135,0000 Americans.[2] Lung cancer was a rare disease until the early part of the 20th century. In 1879, lung cancer represented only 1% of cancers identified at autopsy compared with 14% in 1927.[3]

The link between tobacco use and lung cancer is indisputable. Some of the carcinogenic chemicals found in cigarette smoke include NNK (4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone) and benzo(a)pyrene diol epoxide,[4–6] affecting first- and second-hand smokers.[7] Other toxins that increase the lung cancer risk include arsenic, asbestos, nickel, cadmium, beryllium, silica, and diesel fume exposure.

Lung cancer treatment is multimodal. Physicians diagnosing and treating this disease must collaborate to determine the best treatment for an individual patient.

DIAGNOSIS

Lung cancer is often diagnosed during work-up of an abnormal chest x-ray or CT scan. These studies are often performed in response to a symptom a patient may be experiencing or as a screening examination. Common imaging findings include a lung nodule (solid pulmonary tumor ≤3 cm), mass (tumor >3 cm), or ground glass opacity.

The estimated risk that the nodule represents a cancer guides the evaluation and work-up.[8] Externally validated models can provide patients and physicians with an initial cancer risk assessment.[9,10] Lung nodule management is guideline driven, principally via the widely adopted Fleischner Society guidelines.[8] Generally, low-risk (<5% risk of malignancy) solid nodules between 6 and 8 mm should undergo imaging surveillance. Management options for solid nodules larger than 8 mm in low-risk patients include radiographic surveillance, ^{18}F-FDG PET-CT, or biopsy, depending on nodule size and morphology, assessment of cancer risk, and patient comorbidities. For high-risk patients (≥5%), radiographic surveillance is discretionary for solid nodules smaller than 6 mm, and endorsed for nodules 6 to 8 mm. Solid nodules larger than 8 mm with high malignancy risk should be managed with radiographic surveillance, ^{18}F-FDG PET-CT, and/or biopsy, depending on individual nodule and patient characteristics. Subsolid nodules (ground glass or part solid) at least 6 mm should be followed with serial CT imaging for 5 years independent of patient risk assessment, and biopsied or resected if growth is demonstrated.

Nonsurgical biopsy can be performed through the airway or chest wall. Central nodules or those fed by a nearby airway are amenable to bronchoscopic biopsy often with use of computer-assisted navigation or endobronchial ultrasound. Peripheral nodules may be addressed via transthoracic needle biopsy. The diagnostic yield of electromagnetic navigational bronchoscopy approximates 75% to 85%,[11] while the accuracy of CT-guided biopsy can be as high as 93.5%.[7] Risks of both procedures include bleeding and pneumothorax.[8] The decision to obtain a nonsurgical biopsy is based on the nodule's size and location, the preoperative likelihood of malignancy, and the patient's ability to tolerate operative intervention. A peripheral speculated nodule in an otherwise healthy patient with a significant tobacco history can be managed without preoperative tissue confirmation.

A negative nonsurgical biopsy in a suspicious lung nodule typically necessitates surgical biopsy, such as a wedge resection or rarely an incisional biopsy. For benign nodules, resection is diagnostic and therapeutic. Malignant nodules identified on frozen analysis following wedge can be treated definitively with anatomic lung resection and lymph node sampling in a single operative setting.

Lung masses (i.e., lesions >3 cm) should be strongly considered for expeditious nonsurgical biopsy and invasive mediastinal staging. It is important to consider, however, that other diseases may present with a lung mass: pulmonary infections, inflammatory and autoimmune conditions, lymphoma, and solitary fibrous tumors.

Ground glass opacities (GGOs) are triaged based on their number, their size, and the presence of a solid component within ground glass tissue.[12] An enlarging subsolid (>20 mm) or solid (>6 mm) component should lead to nonsurgical biopsy or surgical resection. ^{18}F-FDG PET-CT is typically performed prior to resection; however, a lack of ^{18}F-FDG uptake does not rule out malignancy in these circumstances.

STAGING

Lung cancer staging is performed clinically and pathologically according to the American Joint Commission on Cancer Staging Manual, which is currently in its eighth edition. Clinical staging is preliminarily based on noninvasive imaging studies. Pathologic staging is driven by histologic results from invasive procedures and is considered definitive.

T, N, M (tumor, node, and metastasis) features drive cancer stage, with a trend toward upstaging as tumor size, nodal status, and metastatic disease burden increase. Particular attention is paid to the mediastinum, as cancers deeply invading the mediastinum (c/pT4) or mediastinal lymph nodes (N2, N3) are typically not amenable to upfront surgery.

Imaging studies have demonstrated good accuracy for predicting mediastinal disease. CT sensitivity, specificity, and accuracy approximate 83%, 82%, and 80% respectively, while ^{18}F-FDG PET-CT yields a sensitivity, specificity, and accuracy of 88%, 92%, and 91%, respectively.[13] A caveat to both tests, however, is that suspicious results do not always correlate with positive disease. Enlarged mediastinal lymph nodes (>1 cm in minor axis) or mediastinal ^{18}F-FDG avidity may represent nonmalignant processes such as inflammatory, granulomatous, or infectious conditions.

There are several methods for invasively staging lung cancer: endobronchial ultrasound (EBUS), endoscopic ultrasound (EUS), cervical mediastinoscopy, anterior mediastinotomy, and video-assisted thoracoscopic exploration and biopsy. EBUS and cervical mediastinoscopy are typically performed when there is mediastinal adenopathy on CT, increased mediastinal FDG uptake on PET-CT, clinical evidence of N1 disease, a lung mass greater than 3 cm, a central lung cancer, or evidence of bilateral lung tumors.[14,15] Anterior mediastinotomy is performed when there are bulky station 5 and/or 6 lymph nodes and there are concerns about a patient's ability to tolerate single-lung

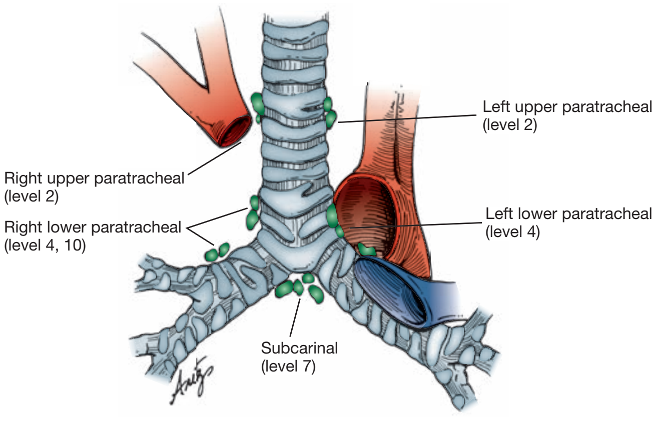

Figure 113-1 Lymph node stations accessible by cervical mediastinoscopy. For consistency the levels should be labeled with the appropriate number when submitted to surgical pathology.

ventilation and thoracoscopic exploration. Thoracoscopic exploration is performed when there is concern for metastatic disease, particularly in the presence of a pleural effusion with negative fluid cytology or evidence of pleural studding. It can also be used to sample station 5/6 lymph nodes or determine mediastinal invasion.

At our institution, EBUS is the initial diagnostic test for mediastinal staging. EBUS with rapid on-site evaluation proceeds logically from N3 to N2 locations, minimizing the need for sampling nodal stations and reducing upstaging risk through needle contamination.[14]

Should EBUS be negative in a patient with suspicious imaging who is a candidate for resection, cervical mediastinoscopy is performed at the time of planned resection. EBUS followed by mediastinoscopy improves sensitivity and reduces sampling error.[16]

■ Cervical Mediastinoscopy

Cervical mediastinoscopy is performed through a small (2.5 cm) transverse neck incision, 1 cm above the sternal notch. The platysma is divided, strap muscles split in the midline, and the pretracheal fascia incised. Blunt dissection is performed over the trachea to create a space for the mediastinoscope. Both nonvideo and video mediastinoscope systems are available (Figs. 113-2 and 113-3). Standard exploration of the mediastinum is performed, assessing the upper and lower paratracheal and subcarinal lymph node stations (2R, 2L, 4R, 4L, and 7). Nodes are harvested and sent for pathologic analysis.

Mediastinoscopy requires a general anesthetic and surgical training to perform correctly and safely. Morbidity and mortality of mediastinoscopy are low: 0% to 5.3% and 0% to 0.05%, respectively.[17] Operators must be able to identify the esophagus, recurrent laryngeal nerve, pulmonary artery, aorta, innominate artery, vena cava, and azygous vein in the process of harvesting lymph nodes (Fig. 113-4).

■ Chamberlain Procedure

The Chamberlain procedure, that is, anterior mediastinotomy, is performed via an incision made over the left second costal cartilage, which is excised. The pleural reflection is swept laterally to access the aortopulmonary window in an extrapleural plane. If this plane is maintained, tube thoracostomy is rarely needed and the procedure can be performed as an outpatient.

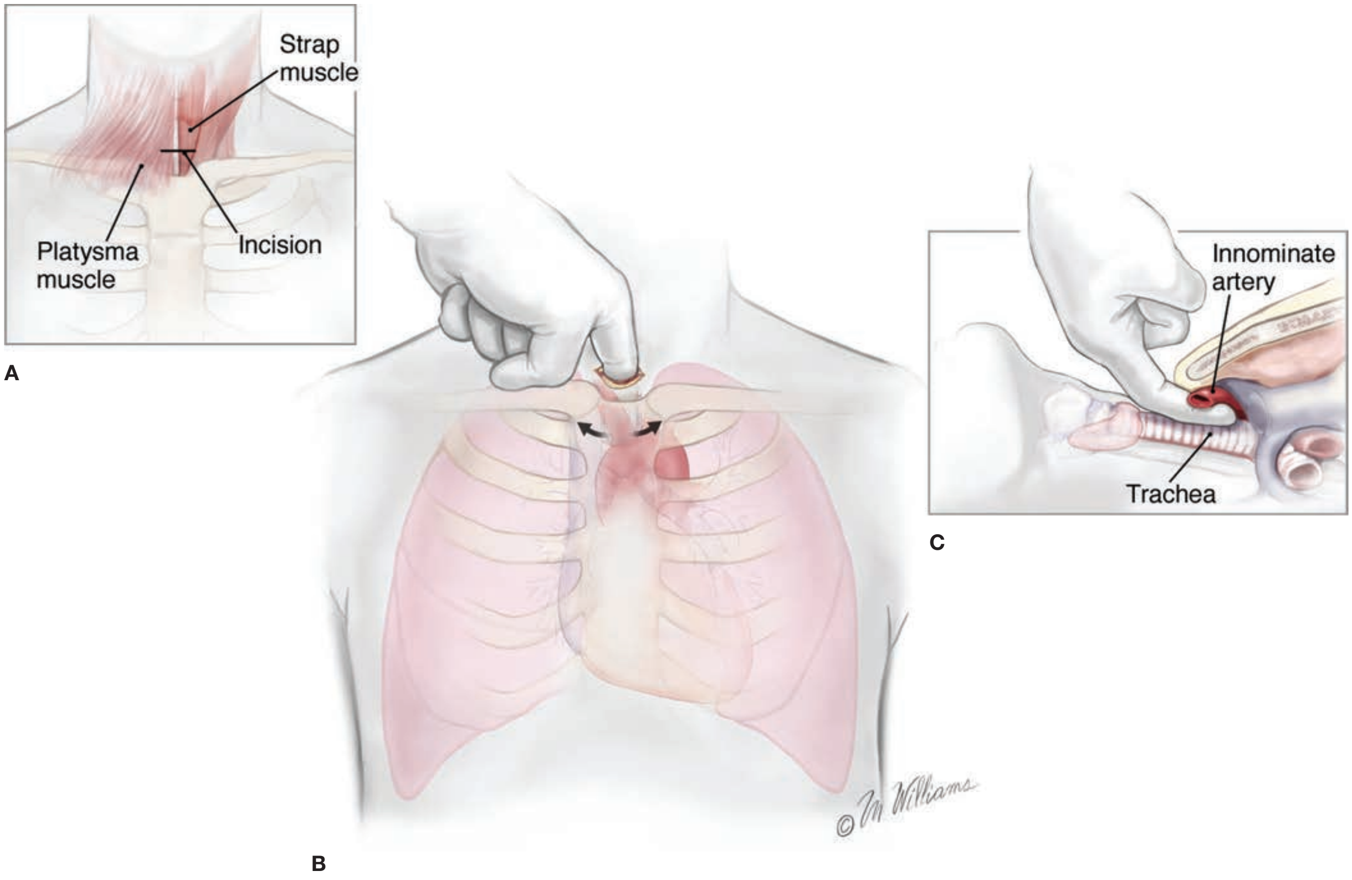

Figure 113-2 Technique of cervical mediastinoscopy. **A.** A 3-cm incision in the midline one fingerbreadth above the sternal notch. **B.** Pretracheal tunnel fashioned with blunt dissection using the index finger. **C.** Dorsal aspect of the finger remains on the trachea while the volar aspect comes in contact with the innominate artery. *(Reproduced with permission from Marcia Williams.)*

Thoracoscopic Surgery

Video-assisted thoracoscopic surgery (VATS) or robotic-assisted thoracoscopic surgery (RATS) can be performed with limited incisions on both sides of the chest. This requires a brief period of single-lung ventilation and may require short-term chest tube drainage. Many patients can undergo this procedure as an outpatient. The benefit of this procedure is excellent visualization of the inside of the chest. The downside is postoperative pain, potential need for a chest tube, and overnight stay in the hospital. Thoracoscopic staging can be performed to evaluate the pleura, level 5 or 6 lymph nodes, right paratracheal nodes, subcarinal nodes, paraesophageal nodes (level 8), and nodes in the inferior pulmonary ligament (level 9) as well as to assess for chest wall or mediastinal invasion.

SURGICAL TREATMENT OF LUNG CANCER

Surgery remains the most durable and thorough method of treating localized lung cancer. Additional benefits of resection include availability of the entire tumor mass for pathologic and molecular testing and provision of more detailed staging information from extensive lymph node sampling. Types of surgical resection include anatomic procedures—segmentectomy, lobectomy, bilobectomy, and pneumonectomy—and nonanatomic wedge resection.

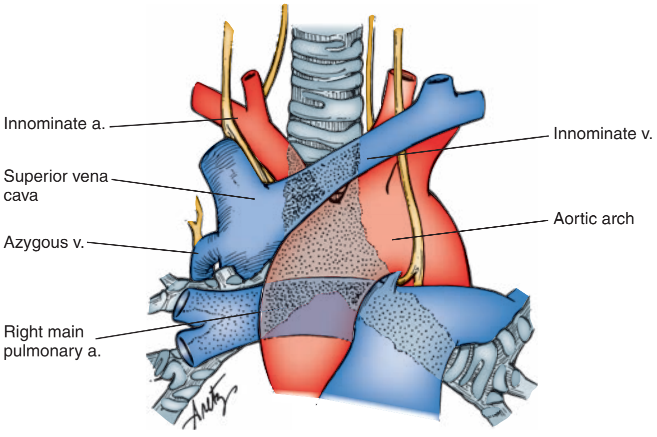

Figure 113-4 The relationship of major vascular structures potentially encountered during mediastinoscopy to the trachea and main bronchi.

When a patient with lung cancer is evaluated for resection, three criteria must be met: surgery must be oncologically beneficial, technically feasible, and physiologically possible. Oncologic benefit and technical feasibility are driven by staging studies and intraoperative findings. A patient's ability to tolerate surgery is determined preoperatively. As critical care and anesthetic techniques continue to improve and minimally invasive surgery advances, all patients with lung cancer should be considered for therapy by the treating specialists. Age bias against treatment including chemotherapy, radiation, and surgery has been documented across many fields of medicine.[18] Age alone should not be the basis for ruling out definitive treatment, and each patient must be evaluated individually.

Patients with advanced disease, who may be candidates for resection after induction therapy, should be referred early in the process so that decisions about potential fitness for operation from oncologic, medical, and technical perspectives can be made.

Tests commonly used to determine a patient's physiologic reserve include ECOG assessment, frailty index calculation, stair climbing, pulmonary function testing, transthoracic echocardiogram, and cardiac stress test.[19] Functional testing, such as stair climbing or shuttle walking, are easily performed in the office and are associated with minimal cost. The height climbed or speed at which the patient climbs a set number of stairs can predict postoperative complications.[20,21] Marginal surgical candidates may be referred for advanced testing such as cardiopulmonary exercise testing.[18,19] Physiologic reserve may be improved by smoking cessation therapy and dedicated exercise programs.[22] Quantitative perfusion lung scans are ordered when advanced pulmonary resections such as bilobectomy or pneumonectomy may be required or for patients with marginal pulmonary function and heterogeneous emphysema.

Anatomic resection involves individual ligation of feeding pulmonary arteries, vein, and bronchus to the region of the lung to be removed. Wedge resection involves removing lung tissue by dividing the lung parenchyma without ligation of the feeding vasculature or airway. Extended resections include anatomic resection with associated structures involved with cancer. These can include the chest wall, vertebral body, diaphragm, pericardium, left atrium, superior vena cava, main bronchus, and pulmonary artery. Resection choice is multifactorial based on tumor location, tumor stage, and a patient's physiologic reserve.

Open Versus Minimally Invasive Surgery

Most pulmonary resections are performed by thoracotomy, but the number of procedures performed by VATS or RATS is rising.[23,24] Open surgery is time-proven and safe, typically performed for central tumors or complex resections, or when VATS/RATS technology or experience is unavailable. VATS procedures were first performed in the early 1990s and have been associated with decreased length of stay, complication rate, and need for blood transfusion.[25–29] RATS has demonstrated similar benefits to VATS and has been performed since the early 2000s. It is estimated that approximately 30% of pulmonary lobectomy procedures are performed in a minimally invasive fashion.[23–25,31] There is increasing evidence that patients who undergo VATS lobectomy are better able to tolerate adjuvant chemotherapy and receive a greater proportion of the planned dose.[28,29]

Type of Resection

A variety of resection techniques must be considered, including lobectomy, segmentectomy, wedge resection, pneumonectomy, sleeve resection, and extended resection.

Lobectomy, Segmentectomy, Wedge Resection

Regardless of the resection modality used, the technical and oncologic principles of lung resection remain the same:[22,23] dissection and individual ligation of the relevant pulmonary arterial, venous, and bronchial branches combined with thorough mediastinal and regional lymph node sampling.[30–32] Lobectomy is the gold standard technique for removing most lung cancers. Segmentectomy is appropriate for invasive cancers less than 2 cm (cT1a–b) with no evidence of lymphatic invasion or for patients with limited pulmonary function. Wedge resection is appropriate for stage 0 lung cancers (adenocarcinoma in situ, adenocarcinoma with lepidic growth pattern, and minimally invasive adenocarcinoma with pure lepidic growth).[33–35]

Segmentectomy represents a more favorable treatment option than wedge resection, providing a wider parenchymal margin and removing regional lymphatic tissue.[39] A prospective randomized trial (CALGB 140503) is being performed to address the issue of lobar versus sublobar resection for peripheral tumors less than or equal to 2 cm. Long-term data are not available yet, but preliminary analysis shows relatively equal perioperative outcomes between lobectomy and segmentectomy.[36] Segmentectomies are often more technically demanding to perform compared to lobectomy. Many surgeons who do not perform a high volume of pulmonary surgery may not possess the expertise required to perform this procedure. Segmentectomy can be performed by open, robotic, or thoracoscopic techniques. Any of the pulmonary segments can be resected individually or in groups. The prototypic segmental resection is the superior segment of the lower lobe. Often, the basilar segments of either lower lobe are resected as a unit. Both segments of the lingula or the upper division of the left upper lobe are often resected together. Posterior or anterior segmentectomy of the right upper lobe also are commonly performed. Once the segmental artery, vein, and bronchus are divided, the lung parenchyma is divided along the intersegmental plane. Techniques for identifying the intersegmental plane include differential inflation and near infrared fluorescence thoracoscopy with indocyanine green injection either intravenously or endobronchially.[37] Three-dimensional CT reconstruction can assist in identifying the segmental anatomy and in localizing tumors near the intersegmental plane[38] (Fig. 113-5).

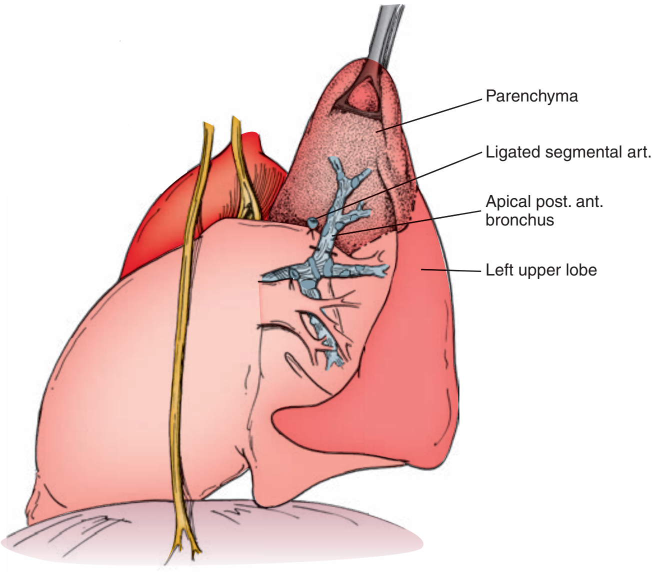

Figure 113-5 Segmental resection. The example shown here is the resection of the apical–posterior segment of the left upper lobe. The segmental pulmonary arterial branch is shown ligated and divided. The segmental bronchus has been dissected out and is the next structure to be divided.

Wedge resection represents the most limited extent of resection. It should be reserved for patients who cannot tolerate an anatomic resection or for patients with known adenocarcinoma in situ or minimally invasive adenocarcinoma. Wedge resection crosses lymphatic channels, does not remove the originating bronchus, and does not permit adequate regional lymph node resection, and parenchymal margins may be limited. These factors limit the value of wedge resection as a planned curative procedure for most primary lung cancers. Anytime a wedge resection is planned for physiologic reasons, nonoperative therapy such as stereotactic body radiotherapy (SBRT) should be considered. A randomized prospective trial of high-risk operable patients deemed not to be candidates for lobectomy is currently accruing patients. The STABLE-MATES trial will compare sublobar resection with SBRT.[39] Adjuvant radiation following wedge resection has been studied in high-risk patients for treatment of early-stage non–small-cell lung cancer (NSCLC).[40] The trial, CALGB 9335, prospectively accrued 58 patients to undergo local radiation treatment with 56 Gy following thoracoscopic wedge resection. Results were mixed: 17% of patients required conversion from VATS to thoracotomy, there were positive resection margins in 13% of patients with T1 and 31% with T2 tumors, and severe dyspnea and pneumonitis occurred in 11% and 14%, respectively, of patients receiving radiation.

Several groups have reported decreased local recurrence with adjuvant brachytherapy at the time of wedge or sublobar resection.[41,42] In these cases, ^{125}I seeds embedded in an absorbable mesh are applied to the line of resection on the lung.[42] This treatment, however, did not result in a meaningful clinical benefit in a randomized clinical trial (ACOSOG Z4032).[43]

Nonoperative therapy should be considered for patients who are not candidates for surgical resection.[44–46] A recent prospective study has shown that SBRT in medically inoperable early-stage cancers was associated with a 3-year locoregional control rate of 87.2% and overall survival of 56%.[46] Drawbacks of radiation therapy include lack of pathologic evaluation of the tumor and local lymph nodes and reduced local control rates.

Pneumonectomy, Sleeve Resection, and Extended Resections

Extended lung resections may be required for larger, locally invasive tumors. Whenever possible, attempts are made to preserve lung tissue using bronchoplastic and arterioplastic surgical techniques. Pneumonectomy is considered a last-resort operation due to a perioperative mortality rate of approximately 5% to 7%. Indications for pneumonectomy include tumor involvement of the main pulmonary artery, extensive endobronchial tumor precluding sleeve resection, involvement of the confluence of the pulmonary veins or a large portion of the left atrium, or long-segment invasion of the interlobar pulmonary artery.

Sleeve resections (bronchoplastic procedures) are more technically demanding but preserve lung tissue. Sleeve resection is possible for each of the lobes. Right upper lobe sleeve resection is the most commonly performed bronchoplastic resection, in which the right main bronchus is divided proximal to the right upper lobe takeoff and the bronchus intermedius is divided distal to the right upper lobe orifice (Fig. 113-6). The right upper lobe (and tumor at the lobar orifice) is removed with a portion of the mainstem bronchus and bronchus intermedius. With any lung-conserving procedure, the margins of the resection should be sent for frozen section for confirmation that no tumor is present. The bronchus intermedius and right main stem bronchus are then anastomosed and usually bolstered with a pedicled autologous flap such as intercostal muscle. Bronchoplastic resections result in lung conservation and are associated with long-term survival rates equivalent to pneumonectomy, with lower morbidity and mortality.

Proximal involvement of the pulmonary artery may also be amenable to arterial sleeve resection. Patch angioplasty with pericardium can be performed to reduce the risk of arterial stenosis. Alternatively, a segment of the artery can be removed and an end-to-end anastomosis performed with or without an interposition graft. Bronchoplastic resections and arterial resections with angioplasties are performed using minimally invasive techniques in many specialized centers.[47–49]

■ Lymph Node Assessment

Lymph node removal is an important part of operative therapy for lung cancer. The extent of lymph node harvest, ranging between systematic sampling and dissection, has been a subject of debate. A 2011 randomized trial among 1000 patients with T1 or T2 tumors showed no significant survival advantage to lymph node dissection as long as systematic and thorough lymph node sampling was performed.[50] It is important to sample stations 2R, 4R, 7, and 10R for right-sided cancers and stations 5, 6, 7, and 10L for left-sided tumors. Failure to include mediastinal lymph nodes as part of a resection results in incomplete information with a risk of understaging and therefore undertreating.

During anatomic resection, multiple inter- and intralobar lymph nodes are encountered; these N1 nodes are labeled by their anatomic location and sent for pathologic examination. During segmentectomy, many surgeons perform frozen section analysis on N1 nodes. If these are positive for cancer, the operation is converted to lobectomy to reduce local recurrence rates.

N2/N3 Disease

Involvement of ipsilateral paratracheal or subcarinal lymph nodes (N2) classifies lung cancer as stage IIIA. These patients are best treated with induction (neoadjuvant) therapy followed by lobectomy or definitive chemoradiation. Contralateral mediastinal disease (N3, stage IIIB) carries a worse prognosis and usually renders a patient oncologically inoperable.

Treatment controversies for stage IIIA disease arise from disagreements about the appropriate role for surgery in this low-volume, heterogenous cancer stage. Questions remain regarding whether bulky, nonbulky, and microscopic nodal disease and single- and multistation lymphatic disease have similar natural histories following induction therapy and whether surgery can improve survival in select patients.

The history of stage IIIA treatment has evolved from surgery alone to induction therapy followed by surgery to definitive chemoradiation. In 1987, Martini et al. demonstrated complete resection in 151 of 500 patients with N2 disease. Complete resection resulted in 28% 5-year survival and 26% absolute survival.[51] Due to 0% survival in patients identified to have N2 disease prior to surgery, Martini subsequently showed that complete resection was possible in 65% of patients after induction therapy. Survival of complete versus incomplete tumor removal was 44% versus 28%, respectively, at 3 years and 26% versus 17%, respectively, at 5 years. Median survival was 27 versus 19 months, respectively.[52]

Subsequent studies confirmed the benefit of induction therapy with surgery in stage IIIA disease. Roth et al. randomized 60 patients with N2 disease to receive 3 cycles of chemotherapy (cyclophosphamide/etoposide/cisplatin) followed by surgery or surgery alone.[53] Preoperative therapy resulted in better outcomes than surgery alone, with median survival of 64 months versus 11 months, respectively. Rossell et al. similarly randomized 60 patients with N2 disease to chemotherapy followed by surgery or surgery alone.[54] A significant survival benefit was seen in the group that received combination therapy: median survival was 26 months versus 8 months, respectively.

A phase 3 trial (Intergroup 0139) was performed to compare induction chemoradiation followed by surgery with definitive chemoradiation.[55] Overall survival was similar in the two groups, but progression-free survival was significantly improved with the combined use of chemoradiation and surgery. When the analysis was restricted to patients who underwent lobectomy as opposed to pneumonectomy, overall survival was improved in the surgical group. Despite this latter result, many centers treat stage IIIA patients definitively with chemoradiation (Fig. 113-7).

In recent years, the pendulum has swung toward considering surgery more seriously as a treatment modality following induction for stage IIIA disease. Koshy et al. retrospectively reviewed 39,000 patients from the National Cancer Database with clinical stage IIIa–N2 disease, reporting improved survival in patients receiving neoadjuvant chemoradiation followed by lobectomy.[56] These results have been replicated by European and North American trials, including SAKK (16/00) and RTOG 0229.[57,58]

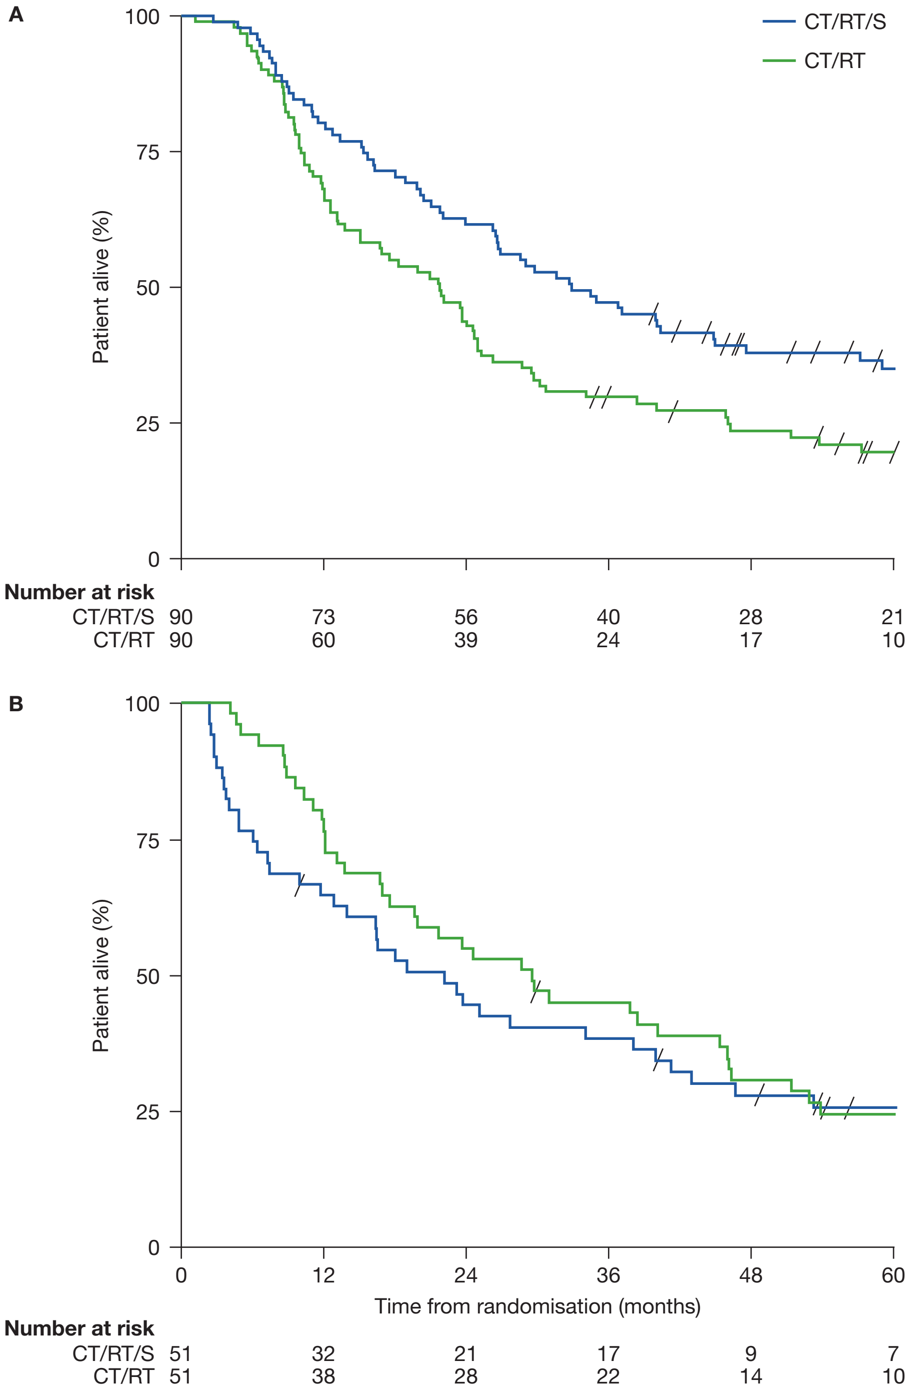

Figure 113-7 Overall survival of a subset of patients from the Intergroup 0319 trial: the intention-to-treat population given lobectomy (**A**) or pneumonectomy (**B**) in group 1 versus matched cohorts in group 2. *Slash marks* represent censored results. CT/RT/S, chemotherapy plus radiotherapy followed by surgery (group 1, *n* = 202); CT/RT, chemotherapy plus radiotherapy (group 2, *n* = 194). *(Reproduced with permission from Albain KS, Swann RS, Rusch VW et al. Radiotherapy plus chemotherapy with or without surgical resection for stage III non-small-cell lung cancer: a phase III randomised controlled trial. Lancet. 2009;374(9687):379–386.)*

Fibrosis that results from induction chemotherapy and radiation can pose technical challenges. This is especially challenging when involved lymph nodes become intimately associated with the pulmonary artery and its branches. It is important to consider obtaining proximal control of the pulmonary artery before attempting resection in these cases. The patient's physiologic reserve, extent of resection, and tumor burden should be carefully considered prior to embarking on a strategy of induction therapy followed by resection.

Pneumonectomy as treatment for stage IIIA disease following induction therapy remains controversial. Despite reported mortality rates as low as 5%, this has not been universally observed.[59–61] Many groups avoid pneumonectomy after induction due to the higher-risk nature of the procedure. Most centers recommend vascularized flap coverage of the bronchial stump in this setting.[60]

■ Chest Wall Resection

Approximately 5% of lung cancers involve the chest wall by direct extension (T3). Involvement may be limited to the parietal pleura or may include the endothoracic fascia, intercostal muscle, and/or ribs. Chest wall involvement by direct extension is *not* a contraindication to resection unless multiple vertebral bodies are invaded; even then, under some circumstances resection may still be completed with concurrent spinal stabilization.

Chest wall pain is the most sensitive predictor of chest wall involvement in a patient with a peripheral lung lesion. Neither CT, MRI, PET-CT, nor bone scan can distinguish between abutment and invasion unless there is gross invasion of bone. Optimal treatment for tumors involving the chest wall (not superior sulcus) is resection followed by adjuvant therapy.[62,63] Metastatic and mediastinal lymphatic disease must be ruled out prior to performing chest wall resection. Three-year survival approaches zero in patients with chest wall and mediastinal lymph node involvement. Greater than 50% 5-year survival can be expected in patients with chest wall involvement with negative mediastinal lymph nodes.

Surgery performed in a patient with suspected chest wall involvement begins with mediastinoscopy to rule out N2/N3 disease. If this is negative, thoracoscopic exploration is often performed on the side of the tumor. This rules out diffuse pleural disease and defines whether the chest wall is invaded; it also allows for lung hilum to be examined to ensure that a clear vascular margin can be obtained.

Resection begins in the extrapleural plane, separating the parietal pleura from the endothoracic fascia in the area of the lesion. If this plane is easily developed, it may be that the parietal pleura is not invaded but affected by inflammatory adhesions. If there is any question about rib invasion when developing the extrapleural plane, then chest wall resection is performed (Fig. 113-8).

The chest wall is resected in continuity with the lung parenchyma. The portion of chest wall removed remains attached to the underlying lung and the specimen is removed en bloc. The chest wall resection should include at least one rib and preferably two ribs above and below the area of invasion. Three- to 5-cm margins

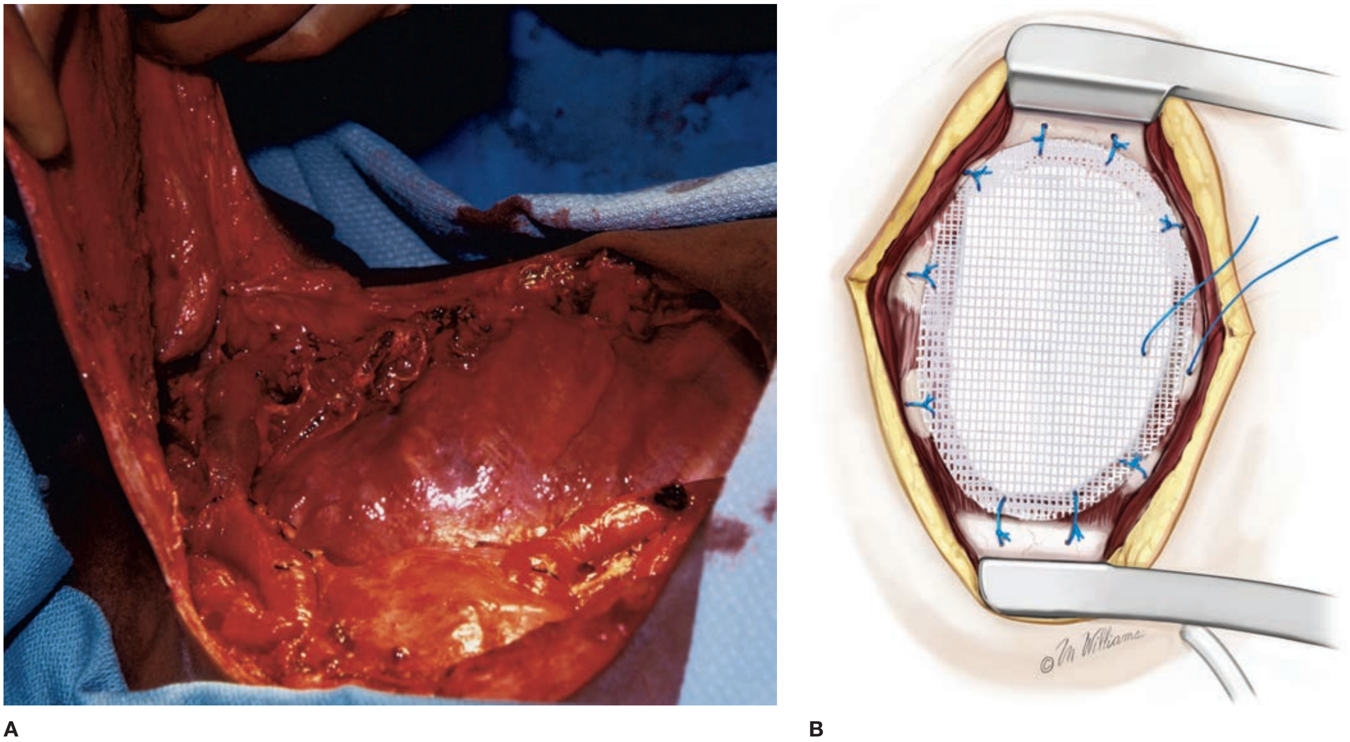

Figure 113-8 **A.** Operative photograph showing the defect left after resection of the left upper lobe in continuity with the anterior chest wall. **B.** This anterior defect requires reconstruction with prosthetic mesh and methyl methacrylate cement. *(**B.** Reproduced with permission from Marcia Williams.)*

should be taken anteriorly and posteriorly. For posterior tumors, the rib should be disarticulated and nerve root ligated.

Once the chest wall bloc is mobilized, it is dropped into the chest and lobectomy with lymph node sampling or dissection completed. Posterior and anterior chest wall defects greater than 5 cm are reconstructed to preserve chest wall function and protect the thoracic viscera. There are multiple prosthetics used for reconstruction, including polypropylene mesh, expanded polytetrafluoroethylene (ePTFE), a sandwich of methyl methacrylate cement and polypropylene mesh, titanium mesh, titanium or stainless steel rib prosthetic plates, and custom 3D-printed prostheses.[64–66] Bioabsorbable prostheses also are available for reconstruction, which have the advantage of being radiolucent.[67] The ideal material for reconstruction has yet to be identified, as the technology does not exist to recreate the rigidity and flexibility of the native chest wall. Posterior defects covered by the scapula may not need reconstruction. Care must be taken to ensure that the scapula tip does not drop into a chest wall defect, causing scapular entrapment.

Chest wall resection, reconstruction, and anatomic resection can be accomplished in selected patients without formal thoracotomy, using thoracoscopic and robotic techniques and low-profile bone-cutting instruments.[68]

Interestingly, en bloc resection of the chest wall increases neither postoperative pain nor overall morbidity of a pulmonary resection. Adjuvant chemotherapy is provided for margin-negative disease.[63] Radiation therapy is provided for positive chest wall margins that cannot be re-resected.[63]

■ Superior Sulcus Tumors

Tumors of the superior sulcus present an oncologic and surgical challenge. Therapy for these tumors has evolved from upfront surgery to palliative care to induction chemoradiation followed by surgery with curative intent.[69] Patients with superior sulcus tumors may present with Pancoast syndrome, which includes shoulder pain, Horner syndrome, and neurologic deficits in the ipsilateral upper extremity usually in the ulnar nerve distribution.[70] MRI of the thoracic inlet, spinal imaging, MRI of the brain, and invasive mediastinal staging must be performed on these patients. N2 disease, C8 root involvement, and motor loss in the ipsilateral hand are contraindications to surgery.

Typical treatment regimens include induction chemoradiation with cisplatin/etoposide and 45 Gy of radiation followed by resection and adjuvant chemotherapy.[71] These tumors may be approached using an anterior cervicothoracotomy, an extended posterolateral thoracotomy, or a combined anterior and posterior approach.[69,70,72] Involved vertebral bodies may be resected and reconstructed at the time of surgery.[73] Reconstruction of the subclavian artery may be required and is associated with good long-term survival provided a complete resection is achieved.[74] Hybrid approaches using minimally invasive techniques have been reported.[75]

■ Tumors Extending into the Mediastinum

Some centrally located primary tumors may invade mediastinal structures (Fig. 113-9). Assessment of the mediastinum is best determined intraoperatively. Without evidence of frank invasion of the mediastinum, we favor evaluation for aggressive resection, provided mediastinal nodal and metastatic disease are ruled out.

Invasion of the heart, great vessels, esophagus, and recurrent laryngeal nerve are contraindications to surgery. Direct involvement of the carina, superior vena cava, and left atrium are not strict contraindications to surgery. The superior vena cava can be partially or completely resected and reconstructed with patch angioplasty or interposition grafting. Autologous or bovine pericardium can be used to reconstruct a portion of the left atrium. Carinal resection and reconstruction usually combined with a right upper lobectomy or right pneumonectomy is performed using similar techniques to sleeve lobectomy with cross-table ventilation of the contralateral

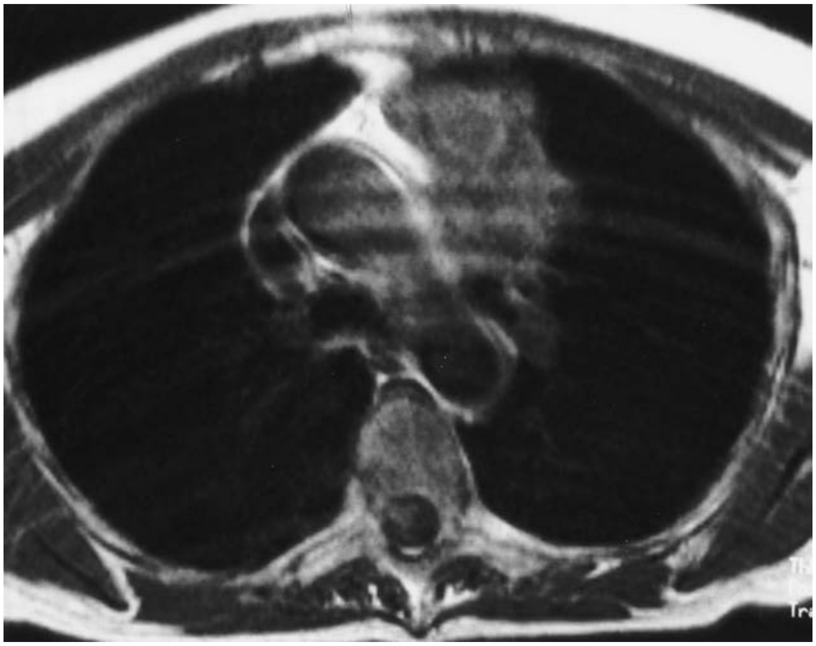

Figure 113-9 MRI scan showing a primary lung tumor involving the aorta by direct extension (T4 primary). The distinction between abutment and invasion often cannot be made until the findings are seen at operation. MRI is no better at delineating invasion than CT.

lung.[76] T4N0–N1 tumors are staged as IIIa and should be evaluated and treated as such.[77]

Vertebral body invasion is not a contraindication to resection. Transverse process or anterior vertebral body involvement can be removed with partial resection of the vertebral body. Extensive involvement of one or more vertebral bodies can be managed with vertebral corpectomy and spinal stabilization with neurosurgeons or orthopedic spine surgeons in one or two stages. These procedures are preferably performed after induction therapy in specialized centers[78,79] (Fig. 113-10).

Involvement of the recurrent laryngeal nerve is a contraindication to surgery. The only exception to this is the occasional situation in which the primary tumor involves the left vagus nerve as it crosses the aortic arch. Such instances merit exploration to determine whether resection is feasible.

■ Palliative Resections

There is a limited role for palliative resections in the modern era of NSCLC. Bleeding or infection of primary tumors usually can be managed with bronchoscopic debulking, airway stenting, external beam radiation, or endobronchial brachytherapy. Chest wall pain can be effectively palliated by radiation therapy.

OUTCOMES

Below we briefly consider postoperative complications, as well as postoperative morbidity and mortality.

■ Postoperative Complications

Major improvements in perioperative thoracic surgical care have led to decreased morbidity and mortality. More sophisticated preoperative patient evaluation has allowed for identification of modifiable risk factors. Increased use of lung-conserving procedures, use of minimally invasive surgical techniques, and increasing number of specialty-trained thoracic surgeons have allowed surgery to be offered to greater numbers of patients. Innovations in pre- and postoperative respiratory care and pain management have contributed to a decrease in perioperative respiratory complications. The introduction of enhanced recovery after surgery (ERAS) protocols has decreased perioperative length of stay, cost, and complications.[80,81] "Prehabilitation" may hold promise in further decreasing perioperative complications and allow more patients to undergo surgery.[22]

Despite these advances, thoracic surgery remains a significant physiologic stress. Patients may not achieve full physiologic and psychological recovery for several months after surgery.[82–86] Additionally, postthoracotomy incision pain—even after minimally invasive procedures—may persist for several weeks after surgery. Patients requiring narcotics beyond the first 6 weeks after surgery should be referred back to the operating surgeon to ensure no organic reason exists for their symptoms. For patients with pure pain-related issues, nonnarcotic analgesics such as gabapentin and referrals to pain management specialists may be helpful adjuncts.

■ Postoperative Mortality

Lobectomy and lesser resections have a mortality rate between 1% and 2%; pneumonectomy mortality approximates 5% to 7%.[66,67] Respiratory complications are the most common cause of

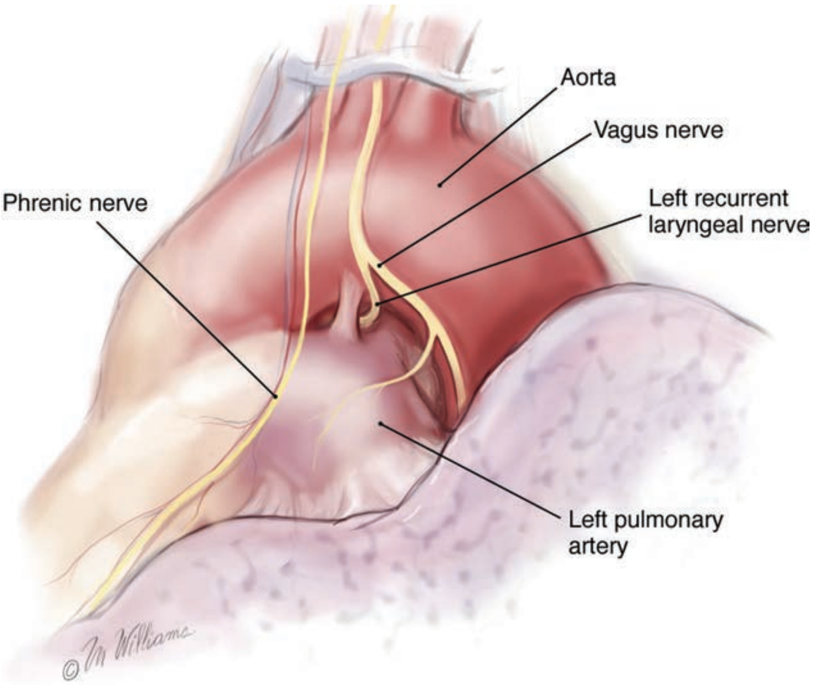

Figure 113-10 The anatomy of the aortopulmonary window showing the relationship of the left recurrent laryngeal nerve to the aortic arch and ligamentum arteriosum. The nerve is easily damaged in this location. Hoarseness may result from tumor involvement of the nerve in this location or from involvement of the vagus nerve at the level of the aortic arch proximal to the location where the recurrent laryngeal nerve originates. *(Reproduced with permission from Marcia Williams.)*

postoperative mortality. Cardiac complications and technical issues such as bleeding hemorrhage, bronchopleural fistula, and empyema account for a small but significant portion of mortality.

Postoperative Morbidity

Approximately 30% to 40% of patients undergoing pulmonary resection experience a postoperative complication. Two-thirds of these are minor, and one-third are nonfatal major.[87] The most common is supraventricular arrhythmia, which occurs in up to 20% of patients. Most respond to simple pharmacologic manipulation and are self-limited. Other minor complications include postoperative air leaks lasting greater than 5 days and atelectasis. Major nonfatal events are typically respiratory related, principally aspiration pneumonitis and nosocomial pneumonia. A small percentage of patients require reintubation for respiratory failure.

There are no definitive predictors of postoperative pulmonary complications, although increasing age, FEV_1 less than 2 L, and diminished diffusing capacity ($\mathrm{DL}_{\mathrm{CO}}$) have been associated with worse outcomes.[88–90] Oxygen consumption ($\dot{V}\mathrm{O}_{2\max}$) less than 10 mL/kg/min on preoperative cardiopulmonary exercise testing is associated with an increased risk of death.

Use of VATS or RATS may decrease pulmonary complications, particularly in patients with limited pulmonary reserve.[91] Chest physiotherapy, nebulized and mucolytic therapies, and patient education have assisted with mucociliary clearance and reduced mucus plugging events following surgery.

Pneumonectomy-specific complications include postpneumonectomy pulmonary edema, postpneumonectomy syndrome, and empyema with or without a bronchial stump leak. Postpneumonectomy edema is characterized by tachypnea, low-grade fever, noncardiogenic pulmonary edema, and hypoxemia in the absence of pneumonia. Supportive care, gentle diuresis, and protective ventilation strategies are the mainstays of care; mortality approximates 50%.[92]

Hemodynamic instability immediately after pneumonectomy may be the result of acute mediastinal shift to the ipsilateral side obstructing venous return. Acute management includes placing the patient in the decubitus position with the operated side elevated and prompt return to the operating room. Postpneumonectomy syndrome is due to anatomic kinking of the contralateral bronchus resulting from excessive mediastinal shift and rotation. It is unclear exactly why this complication develops, but it appears to be due to fibrosis of the mediastinum following pneumonectomy combined with progressive shift of the mediastinum toward the surgical side. Symptomatic patients may be helped by stabilizing the mediastinum with insertion of sterile saline implants or Lucite balls into the pneumonectomy space, which repositions the mediastinum closer to the midline and relieves the functional obstruction.

Postpneumonectomy empyema may occur in the perioperative period from contamination at the time of surgery or a bronchial stump leak. It can occur late, from local recurrence, instrumentation, or bacteremia, or its source may be idiopathic. A sudden decrease in the height of the air–fluid level on chest radiograph, signifying a bronchopleural fistula, and a cough productive of thin brownish sputum should trigger prompt investigation. Treatment involves prompt pleural drainage, initiation of broad-spectrum antibiotics, and evaluation of the bronchus via flexible bronchoscopy. Pleural drainage should be instituted with the affected side in a dependent position. Additionally, the operator must be cognizant of the anatomic derangements after pneumonectomy such as an elevated diaphragm and mediastinal shift that may put thoracic or abdominal viscera at risk during pleural drainage. Decisions regarding the need for definitive drainage via window thoracostomy versus autologous pedicled flapping and chest closure or nonoperative therapy remain challenging.

TABLE 113-1 Overall Survival by Clinical Stage

Stage	24-Month Survival	60-Month Survival
IA1	97%	92%
IA2	94%	83%
IA3	90%	77%
IB	87%	68%
IIA	79%	60%
IIB	72%	53%
IIIA	55%	36%
IIIB	44%	26%
IIIC	24%	13%
IVA	23%	10%
IVB	10%	0%

Data from Goldstraw P, Chansky K, Crowley J, et al. The IASLC Lung Cancer Staging Project: Proposals for Revision of the TNM Stage Groupings in the Forthcoming (Eighth) Edition of the TNM Classification for Lung Cancer. J Thorac Oncol. 2016;11(1):39–51.

PROGNOSIS

Outcomes following pulmonary resection for lung cancer are dictated by TNM stage. In the absence of stage IV disease, lymphatic involvement drives prognosis. Histology also has prognostic significance—in particular, the presence of neuroendocrine carcinoma/small-cell lung cancer and micropapillary adenocarcinoma with extensive spread through the air spaces portend a worse prognosis. Survival estimates vary among surgical series. The current staging system divides stage IA disease into stages IA1, IA2, and IA3 to allow for granular discrimination of outcomes. In the validation of the most recent staging system, 17,477 clinically staged and 31,836 pathologically staged patients were analyzed.[93] Survival estimates, which include patients treated with both surgical and nonsurgical interventions, are shown in Table 113-1.

Sites of Recurrence

Patients with lung cancer frequently die of disseminated disease. A study from Memorial Sloan Kettering reported recurrence patterns in patients with initially localized lung cancer: 44% distant sites, 30% distant and locoregional sites, and 26% locoregional.[94] More than 30% of patients with adenocarcinoma develop brain metastasis. Other sites of metastasis include bone, lung, liver, and adrenal glands. Patients with higher-stage disease at diagnosis have a greater likelihood of developing disseminated disease. This recognition has led to routine administration of adjuvant treatment regimens following surgical resection for patients with stage IIA and above disease.

Local recurrence may be amenable to repeat resection. Sites of local recurrence include the chest wall, adjacent lung tissue, mediastinum, and great vessels of the chest. Determination of resectability is made in a multidisciplinary setting, with consideration of a patient's performance status and ability to obtain a complete resection. SVC syndrome and recurrent laryngeal nerve invasion are not amenable to surgery, but radiation and chemotherapy may be helpful.

POSTSURGICAL FOLLOW-UP

Postresection follow-up is dictated by pathologic cancer stage. Generally, stage IA and IB disease, treated with surgery alone, should be followed with history, physical examination, and chest

CT with contrast every 6 to 12 months for 2 years. Should there be no evidence of recurrent disease, annual examination and noncontrast CT should be performed for an additional 3 years.[43] Patients receiving adjuvant chemotherapy for stage IB–IIIA disease typically undergo similar surveillance, with a provisional recommendation to undergo initial CT imaging every 3 to 6 months for the first 2 years following treatment completion. The American Association for Thoracic Surgery surveillance protocol recommends an annual low-dose screening CT for lung cancer survivors between the ages of 50 and 79 years who have completed 4 years of standard follow-up.[95,96] PET and MRI are not routinely ordered but may be required if additional nodules or metastatic lesions require assessment.[96]

FUTURE DIRECTIONS

Continued refinement in surgical technique and perioperative management will allow greater numbers of patients to benefit from surgical intervention. Ongoing collaboration between surgeons, medical and radiation oncologists, and basic scientists will continue to expand treatment options for this virulent disease. Immunotherapy and targeted therapies are showing promise in treating patients with disseminated disease with molecular mutations. While surgery remains the standard therapy for fit patients with localized NSCLC, risk factor modification is the best way to prevent disease. The importance of smoking cessation efforts and improved occupational environmental controls cannot be overemphasized.

CHAPTER 114

Treatment of Non–Small-Cell Lung Cancer: Chemotherapy and Immunotherapy

Laurie L. Carr

INTRODUCTION

Although lung cancer remains the leading cause of cancer death in the United States, a reduction in smoking rates and recent medical advances have improved the overall mortality rate. The decline in lung cancer mortality rates has accelerated from a 3% decrease (2008–2013) to 5% (2013–2017).[1] Noted medical advances driving the decrease include lung cancer screening and stereotactic body radiotherapy. However, improved systemic therapy with immune checkpoint inhibitors and targeted agents also have had an impact. These improvements have led to prolonged survival in those with metastatic disease. Treatment with targeted agents or immunotherapy has led to a significant percentage of these patients surviving 5 years or more.[2–4] These novel therapies have emerged to make lung cancer therapy better tolerated and more effective, even among those with significant comorbidities. Thus, although the morbidity and mortality of lung cancer remain high, novel approaches to therapy have begun to make a substantial impact.

Chemotherapy is used for three main reasons in the treatment of non–small-cell lung cancer (NSCLC): (1) as adjuvant therapy in early-stage disease, either preceding or following potentially curable, surgical resection to prevent disease recurrence; (2) as concurrent therapy with radiation in locally advanced disease to radiosensitize the tumor for improved local response and prevent metastatic disease recurrence; and (3) as palliative therapy in the setting of advanced disease to ease symptoms and prolong survival. Immunotherapy has emerged as an important addition to conventional chemotherapy for treatment of advanced disease. This chapter focuses on the role of systemic chemotherapy and immunotherapy in the treatment of NSCLC in each of these settings.

ADJUVANT THERAPY FOR NON–SMALL-CELL LUNG CANCER

Surgery remains the standard of care for patients with early-stage disease who do not have medical contraindications. In this setting, surgery provides definitive treatment and allows for more accurate pathologic staging. Staging is central to the therapeutic approach to NSCLC and entails determination of the extent of invasion of the mediastinal lymph nodes. Mediastinoscopy or fine-needle aspiration (FNA) of lymph nodes by endobronchial ultrasound (EBUS) can be used to sample mediastinal lymph nodes before surgical resection. As for all surgical interventions for thoracic malignancy, complete nodal sampling or lymph node dissection is an integral part of the procedure. Reliance on noninvasive imaging alone may be inadequate for an accurate assessment of the mediastinum (Fig. 114-1).

Adjuvant Chemotherapy

It is well recognized that despite complete resection, most patients with NSCLC will develop disseminated disease. The risk of developing disseminated disease can be predicted, with some accuracy, based on the stage of the disease determined at the time of the initial resection. However, the value of the staging information depends on the completeness of the staging procedures carried out at the time of resection. Even with stage I disease, as many as 20% of patients die of disseminated disease within 5 years. With stage II disease, less than 60% of patients are alive at 5 years; with stage IIIA disease, at best, 41% of patients are alive at 5 years.[5] These numbers illustrate the need for additional therapy to improve the overall survival (OS) achieved by surgery.

To this end, a body of data has emerged to define the role of chemotherapy in the adjuvant setting. The rationale behind this approach is to treat patients who are deemed to be at high risk for recurrence and dissemination of disease in the hope of eliminating micrometastatic disease. Multiple trials randomizing patients to surgery versus surgery followed by platinum-based chemotherapy have been conducted. More recently, molecular targeted agents have been studied in the adjuvant setting to determine the impact of these agents in early-stage disease (Table 114-1).

International Adjuvant Lung Cancer Trial

The International Adjuvant Lung Cancer Trial (IALT) randomized 1867 patients with stage I, II, or III NSCLC to observation or chemotherapy after surgical resection.[6] Due to the lack of consensus regarding the use of adjuvant radiotherapy, the choice of a specific radiation regimen was made by each participating institution at the time of protocol development. The chemotherapy regimens used consisted of cisplatin 80, 100, or 120 mg/m^2 offered on 1 of 4 different schedules with vindesine, vinblastine, vinorelbine, or etoposide. Patients were treated with 3 or 4 cycles. Of the various choices, the combination of cisplatin and etoposide was used to treat nearly 50% of the patients. When offered, radiation was given after chemotherapy in the group randomized to postoperative treatment. Overall, the results favored the use of adjuvant chemotherapy, with

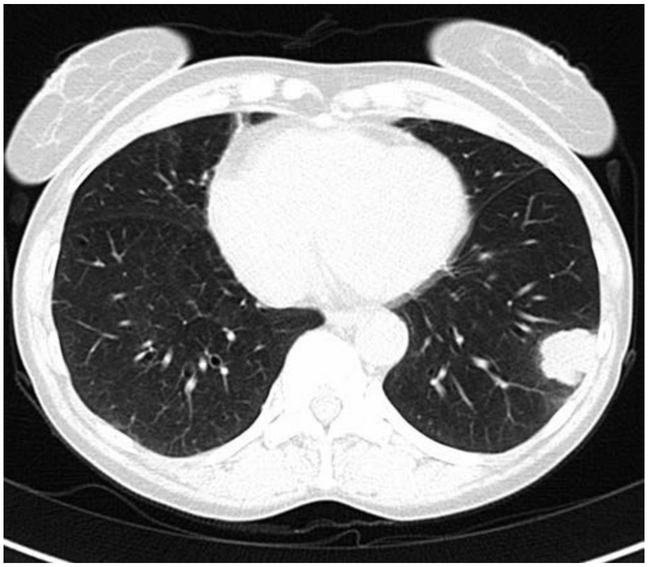

Figure 114-1 CT scan of a 59-year-old female with ongoing smoking and chronic cough. The image shows a large nodule in the left lower lobe extending into the pleura. The patient underwent a mediastinal lymph node dissection and left lower lobectomy. She was found to have several hilar lymph nodes involved with tumor at the time of resection (stage IIA). She received four cycles of cisplatin-based adjuvant chemotherapy following surgical resection.

TABLE 114-1 Randomized Trials of Adjuvant Therapy

	Overall						
					Survival (%)		
Trial	Number of Patients	Stage	Therapy	Survival (Months)	2 Years	3 Years	5 Years
International Adjuvant Lung Cancer Trial[6,7]	1867	IA, IB, II, III	Observation	45	66.7		40.4
			Chemotherapy	54	70.3		44.5
CALGB 9633[8]	344	IB–T2N0	Observation	78[a]	84	73	58[a]
			Chemotherapy	95[a]	90	80	60[a]
NCIC JBR 10[9]	482	IB, II (no T3N0)	Observation	73			54
			Chemotherapy	94			69
ANITA[10]	840	IB, II, IIIA	Observation	43.7			
			Chemotherapy	65.7			
LACE	4584	IA, IB, II, III	Observation			Absolute improvement	
Meta-analysis[12]			Chemotherapy			3.9%	5.4%
ADJUVANT/	222	II, IIIA	Chemotherapy	79.2		67.5	52.4
CTONG1104[16]			Gefitinib	75.5		68	53.8
ADAURA[17,18]	682	IB, II, IIIA			Disease-free survival		
			Placebo		52[a]		
			Osimertinib		89[a]		

[a] Statistically significant.

CALGB, Cancer and Leukemia Group B; NCIC, National Cancer Institute of Canada; ANITA, Adjuvant Navelbine International Trialist Association; LACE, Lung Adjuvant Cisplatin Evaluation; CTONG, Chinese Thoracic Oncology Group.

a hazard ratio (HR) for death of 0.86 (0.76–0.98). At 5 years, the group that received chemotherapy had a statistically significant improvement in survival of 44.5% versus 40.4%. The toxicities associated with chemotherapy included the expected risks of neutropenia and nausea/vomiting. However, 7 patients (0.8%) died due to chemotherapy-related acute toxicities; this was predominantly seen in those who received cisplatin at 120 mg/m^2. This positive trial demonstrated an absolute benefit at 5 years and provided support for the use of cisplatin-based treatment in the adjuvant setting.[7]

NCIC JBR 10

In this intergroup study, 482 patients with stage IB or II (excluding T3N0) NSCLC were randomized to either surgery or surgery followed by 4 cycles of chemotherapy.[8] Again, the treatment studied included cisplatin (50 mg/m^2 days 1 and 8) and vinorelbine (25 mg/m^2 weekly); 1 cycle was 4 weeks. NCIC JBR 10 was a positive study, with 5-year survival favoring the chemotherapy group (69% vs. 54%), as well as a statistically significant improvement in disease-free survival (DFS) and OS. Toxicity was associated with this regimen with 2 treatment-related deaths and more than 70% of patients experiencing either grade 3 or 4 neutropenia.

ANITA

The Adjuvant Navelbine International Trialist Association (ANITA) study randomized 840 patients with stage IB, II, or IIIA NSCLC to 4 cycles of chemotherapy or observation after surgery.[9] Similar to the other trials, the chemotherapy regimen consisted of cisplatin (100 mg/m^2, day 1) and vinorelbine (30 mg/m^2, weekly) for a 4-week cycle. The choice of radiotherapy was left to the discretion of the treating physicians. In the final analysis, 24% of patients in the chemotherapy arm and 33% of patients in the observation arm received radiation. Patients randomized to chemotherapy had a significant improvement in median survival to 66 months, compared with 44 months in the control group. At 5 years, the absolute benefit in survival was 8.6%, and in a subset analysis, this benefit seemed to be mainly noted in stage II and IIIA patients.

TREAT Study

More recently, the Trial on Refinement of Early-Stage NSCLC Adjuvant Chemotherapy (TREAT) randomized patients to cisplatin (75 mg/m^2) and pemetrexed (500 mg/m^2) every 3 weeks versus cisplatin (50 mg/m^2 days 1 and 8) and vinorelbine (25 mg/m^2 days 1, 8, 15, and 22) every 4 weeks. The study was designed to determine if substitution for the vinca alkaloid could improve upon side effects and dose delivery in the adjuvant setting. In all, 132 patients (stages IB–IIIA) were randomized to 4 cycles of either regimen. Ninety-five percent of those in the pemetrexed arm vs. 75% in the vinorelbine arm received all cycles of therapy without significant dose-limiting toxicity. The hematologic grade 3 or 4 toxic effects were significantly less with pemetrexed, yet no difference was seen in progression-free survival (PFS). This regimen is recommended for adjuvant therapy in resected adenocarcinoma.[10]

Lung Adjuvant Cisplatin Evaluation Meta-analysis

In 2008, the Lung Adjuvant Cisplatin Evaluation (LACE) Collaborative Group published results of a pooled analysis of large trials (>300 subjects) investigating the use of cisplatin-based adjuvant chemotherapy versus no further therapy following complete resection of NSCLC.[11] The individual data from more than 4500 subjects was analyzed with a median of 5.2 years follow-up. The investigators found an absolute benefit of 5.4% improvement in OS at 5 years in the treatment group. There was no interaction seen in regard to gender, age, histology, or type of surgery. However, the degree of benefit varied with stage; the HR for stage IB was 0.93 (95% confidence interval [CI], 0.78–1.10), for stage II the HR was 0.83 (95% CI, 0.73–0.95), and for stage III the HR was 0.83 (95% CI, 0.72–0.94). This analysis confirmed the benefit of cisplatin-based adjuvant chemotherapy following complete resection in fit patients with stage II and III NSCLC. Currently, the National

Comprehensive Cancer Network (NCCN) and American Society of Clinical Oncology (ASCO) guidelines recommend cisplatin-based adjuvant chemotherapy for stage II and IIIA NSCLC. Unfortunately, the addition of bevacizumab, an antiangiogenesis agent, to adjuvant chemotherapy did not improve outcomes and is not recommended in this setting.[12]

CALGB 9633

The Cancer and Leukemia Group B (CALGB) conducted a trial to test the benefit of carboplatin-based adjuvant chemotherapy exclusively in stage IB (T2N0) patients.[13] Other studies included these patients along with those with more advanced disease, and in subset analyses, the true benefit of chemotherapy after surgery in this population was questioned. Originally, this study was intended to enroll 500 patients. However, due to poor accrual, this number was modified and in the final analysis, 344 patients were treated. Patients randomized to the chemotherapy arm received carboplatin dosed to a target area under the curve (AUC) of 6 mg/mL/min and paclitaxel 200 mg/m^2 every 3 weeks for 4 cycles. After 74 months of mean follow-up, the difference in 5-year survival between the chemotherapy and observation arms (59% vs. 57%; HR, 0.83) was not statistically significant. Therefore, the routine practice of treating patients with stage IB disease is no longer recommended. However, in a subset analysis of patients with tumors greater than 4 cm in size who received chemotherapy there was a statistically significant benefit overall (HR, 0.69; $p = 0.43$). This benefit was not shared in those with tumors less than 4 cm in size. Thus, in practice, many oncologists choose to treat patients with large-stage IB tumors with adjuvant chemotherapy based on this subset analysis.

In summary, multiple randomized studies of adjuvant chemotherapy demonstrated improved disease-free survival when four cycles of cisplatin-based doublets are administered following surgical resection. This benefit is greatest in those with stage II and III disease; however, in stage IB disease with high-risk features (i.e., >4 cm in size), adjuvant therapy is also recommended. In those with contraindications to cisplatin (i.e., hearing loss or chronic kidney disease), carboplatin is used.

■ Adjuvant Molecular Targeted Therapy

The use of oral agents that inhibit driver mutations in metastatic NSCLC, such as epidermal growth factor receptor (EGFR) and anaplastic lymphoma kinase (ALK) tyrosine kinase inhibitors (TKIs), has made a substantial improvement in survival and quality of life for patients with advanced disease driven by activating mutations. Efforts to integrate targeted therapy into the treatment of early-stage disease are ongoing, including in the adjuvant setting.

RADIANT

RADIANT was the first large, randomized trial of EGFR inhibition following surgical resection in NSCLC. In this study, patients with stage IB–IIIA NSCLC who had undergone surgical resection and platinum-based adjuvant chemotherapy were randomized to two years of erlotinib versus placebo. A total of 973 patients whose tumors expressed EGFR protein by immunohistochemistry (IHC) or EGFR amplification by fluorescence in situ hybridization (FISH) were enrolled. Although not required for enrollment, tissue was also tested for EGFR activating mutations. The study was negative for the primary endpoint of improved DFS (HR, 0.90; 95% CI, 0.74–1.10; $p = 0.324$). Among the 161 patients (16.5%) in the EGFR mutation–positive subgroup, DFS favored erlotinib with a median of 46.4 months versus 28.5 months (HR, 0.61; 95% CI, 0.38–0.98; $p = 0.039$). However, this was not statistically significant due to hierarchical testing. Also of concern, only 40.6% of those in the erlotinib arm completed the planned 2 years of treatment; the authors noted patients had a low tolerance for prolonged treatment in the adjuvant setting due to side effects.[14]

SELECT

The Surgically Resected EGFR-Mutant Lung Cancer with Adjuvant Erlotinib Cancer Treatment (SELECT) study was a nonrandomized, open-label trial of patients with stage IA–IIIA NSCLC who had completed planned adjuvant chemotherapy and radiotherapy as needed. This small, single-arm study of adjuvant erlotinib therapy in 100 patients with EGFR mutations was able to demonstrate improvement in 2-year DFS compared with historic controls. Although this was a small nonrandomized study, several important outcomes were observed. First, with appropriate dose reductions, 69% of subjects were able to complete 2 years of erlotinib therapy. Second, although 40 patients had disease recurrence in the 5.2 years of median follow-up, only four occurred while on erlotinib. The median time to recurrence was 25 months after stopping erlotinib. Importantly, when retreated with erlotinib upon disease recurrence, the median duration of response was still 13 months. Larger, randomized trials were needed to determine if adjuvant therapy with an EGFR TKI changes the natural course of disease and improves survival or merely delays recurrence.[15]

ADJUVANT/CTONG1104

One such large, randomized, phase 3 study was performed in China in which 222 stage II–IIIA patients, whose lung cancer expressed mutated EGFR, were enrolled in the ADJUVANT/CTONG1104 study comparing 2 years of gefitinib to 4 cycles of cisplatin and vinorelbine. The study was positive for longer median DFS of 28.7 months in those treated with gefitinib versus 18 months (HR, 0.60; 95% CI, 0.42–0.87; $p = 0.0054$). However, the 2 groups had similar 3-year DFS, and the OS was not significantly improved at 75 months versus 62 months (HR, 0.92; $p = 0.674$). Thus, in this study, adjuvant gefitinib delayed disease recurrence but did not increase the number cured.[16]

ADAURA

The most exciting data in the use of TKIs in the adjuvant setting are the initial results of a large, placebo-controlled, phase 3 trial of patients with stage IB–IIIA NSCLC who had undergone surgical resection and adjuvant chemotherapy for EGFR-mutated disease.[17,18] In this study, a third-generation EGFR TKI, osimertinib, or placebo was given for 3 years. The trial was unblinded early due to notable improvement in DFS, the primary endpoint. The 2-year DFS was 89% with osimertinib versus 53% with placebo (HR, 0.21; $p < 0.0001$). The OS data are immature. As osimertinib is well tolerated, these data may change the standard of care, particularly for stage III disease due to the high recurrence rates. These data have also changed recommendations expanding molecular testing to early-stage disease.

■ Future Directions in Adjuvant Therapy for NSCLC

Adjuvant cisplatin doublet chemotherapy is currently the standard of care for stage II and IIIA patients. The role of adjuvant treatment of stage IB patients has yet to be defined more clearly, but based on subset analyses, patients with tumors greater than 4 cm may benefit from chemotherapy. For those with EGFR-mutated disease, there are compelling data regarding improved 2-year DFS with adjuvant osimertinib. We are awaiting the overall survival data from this study. Additional large trials of targeted therapy in the adjuvant setting are ongoing, including ALCHEMIST, the Adjuvant Lung Cancer Enrichment Marker Identification and Sequencing Trial, which includes a study of an adjuvant TKI in ALK translocated disease. For those without driver mutations, the future of adjuvant therapy lies in understanding the role of immune checkpoint inhibitors. Currently, four phase 3 randomized studies are underway to determine if adjuvant immunotherapy can improve outcomes in early-stage disease.

LOCALLY ADVANCED NSCLC

The term *locally advanced* includes several different presentations of primary lung cancer, but all have in common the absence of disease outside of the chest. Included in this category are those with stage IIIA–IIIC disease. These tumors involve mediastinal lymph nodes, either ipsilateral (N2) or contralateral (N3), or large primary tumors that directly invade important thoracic structures. For example, T3 tumors involve the chest wall or the phrenic nerve, or are greater than 5 cm in size. T4 tumors invade the mediastinum and affect structures that are not usually considered resectable (e.g., aorta, esophagus, vertebral bodies). Mediastinal lymph node invasion should be determined before surgical resection by way of mediastinoscopy or EBUS with FNA, which also allows contralateral mediastinal lymph nodes to be sampled.

About 40,000 cases of stage III disease occur per year in the United States. The best treatment approach to locally advanced disease has not yet been determined. A wide array of combined modality approaches has been used in stage IIIA patients (particularly those with N2 nodes). These include varying combinations of chemotherapy, radiation, and surgery. More recently, the introduction of immune checkpoint inhibitors into the treatment of locally advanced disease has led to changes in treatment plans and improved outcomes. Integrating immunotherapy into the treatment of locally advanced disease is an active area of research in NSCLC.

■ Locally Advanced Resectable NSCLC

The roles of sequential chemotherapy followed by surgery and concurrent chemoradiation followed by surgery in treating locally advanced, resectable NSCLC are described below.

Chemotherapy Followed by Surgery

Neoadjuvant therapy, also referred to as *induction therapy*, has been applied to the treatment of NSCLC. It entails treating patients with chemotherapy even though there is no clinical evidence that the primary cancer has spread. Lung cancers are particularly attractive targets for neoadjuvant therapy, as many present as locally advanced disease confined to the chest, and patients run a considerable risk of developing distant disease within a short time. Neoadjuvant therapy affords a unique opportunity to assess the sensitivity of the cancer to the drug regimen. This information may be useful in the postoperative period when the possibility of adjuvant therapy is under consideration. Assessing response to neoadjuvant therapy can also more rapidly translate into clinical research findings, particularly if pathologic response is used as a surrogate marker for survival. Another consideration is that the required dose-intensive regimens are apt to be better tolerated before surgery and may improve drug delivery due to the preserved vasculature of the tumor, thus decreasing the prospect of developing drug resistance. However, the possibility that adverse effects of induction chemotherapy could lead to a delay in surgery or a postoperative complication must be considered.

There have been two phase 3 randomized trials of neoadjuvant chemotherapy in patients with locally advanced NSCLC (stage IIIA). Some patients had N2 disease alone, while others had T3N0 disease (now considered stage IIB by the American Joint Committee on Cancer 8th edition TNM staging).[19,20] In contrast to results in patients with disseminated NSCLC, in whom the response to chemotherapy at best approaches 30%, 60% to 70% of patients with locally advanced disease responded favorably. Importantly, in both trials, the median survival was improved in patients who received neoadjuvant treatment. The study of neoadjuvant chemotherapy was expanded to earlier stages (IB–IIIA) in several additional trials.[21,22] Although several of these studies were closed early due to the adoption of adjuvant therapy during this time, an improvement in OS was seen in those with stage II/IIIA disease. For example, in a randomized study of surgery alone or surgery plus preoperative cisplatin and gemcitabine, the subgroup of stage IIB/IIIA patients had an improvement in 3-year PFS (36.1% vs. 55.4%; $p = 0.002$).[22] These data are consistent with results seen in studies of adjuvant chemotherapy.

As described above, one potential advantage of neoadjuvant therapy is timely outcome data through assessment of pathologic response at the time of surgical resection. In a 2012 study of histopathologic response to neoadjuvant chemotherapy, the percentage of residual viable tumor cells was associated with OS and DFS in a multivariate analysis.[23] Five-year OS and DFS were significantly longer in patients with $\leq$10% viable tumor cells after neoadjuvant therapy compared to those with $>$10%. To facilitate the adoption of new treatment for patients with resectable tumors, it has been proposed to use "major pathologic response" (MPR) (10% or less residual viable tumor after neoadjuvant therapy) as a primary endpoint for drug development in this area.[24] Current immunotherapy trials in the neoadjuvant setting have incorporated MPR as a surrogate endpoint for survival.

Early trials of immunotherapy in the neoadjuvant setting have used immune checkpoint inhibitors alone, either programmed death 1 (PD-1) or programmed death ligand 1 (PD-L1) inhibitors. A pilot study of single-agent nivolumab (PD-1 inhibitor) in 21 patients prior to surgery demonstrated a MPR of 45% with few side effects and no delay in surgery.[25] Early results of a single-arm study of neoadjuvant atezolizumab (PD-L1 inhibitor) revealed an MPR of 24% (95% CI, 7–50) among the first 21 subjects. Again, the treatment was well tolerated with no delay in planned surgery.[26] Other trials have combined immune checkpoint inhibitors with cytotoxic chemotherapy in the neoadjuvant setting. In a 30-patient, single-arm, phase 2 trial of atezolizumab (PD-L1 inhibitor) combined with carboplatin and nab-paclitaxel prior to resection, 57% of patients (95% CI, 37–75) had an MPR. Additional phase 2 studies of combined chemoimmunotherapy in the neoadjuvant setting have demonstrated high MPR rates, leading to the initiation of multiple, randomized, phase 3 studies with the potential to change the treatment of locally advanced, resectable NSCLC.[27]

Concurrent Chemoradiation Followed by Surgery

Various theoretical considerations have led to trials of chemotherapy and radiation followed by surgery (trimodality therapy): (1) Tumor cell subpopulations in locally advanced NSCLC may respond differently to radiation and chemotherapy, and cells resistant to one treatment method may be sensitive to the other. (2) Chemotherapy may promote the emergence of radiosensitive cells, thereby increasing the total number of cells killed by continued radiation treatments. (3) Induction of cell cycle synchronization by certain drugs may increase cell killing by radiation and induce recruitment of tumor cells in G_0.

The Southwest Oncology Group (SWOG) conducted a trial using the cisplatin/etoposide regimen they had developed with concurrent radiotherapy; the trial included both stage IIIA and IIIB patients.[28] All 126 patients underwent mediastinoscopy for histologic evaluation of mediastinal lymph nodes. The response rate to the preoperative therapy was 59%, with 29% having stable disease. The resection rate was 85% in the stage IIIA patients and 80% in the stage IIIB patients. The 3-year survival was similar in both stage IIIA and IIIB patients at 27% and 24%, respectively. The absence of tumor in the mediastinal nodes at the time of surgery was associated with improved survival. Failure was more common in distant, rather than locoregional, sites with relapse occurring in 26 patients.

It remains to be proven that surgery is a necessary part of the treatment of these patients. The high response rate to chemoradiotherapy in the high-performance patients entered into these clinical trials raises the question of whether chemotherapy and radiation might be able to achieve a similar endpoint with regard to local control. A large intergroup study addressed this question.[29] In this trial, 396 patients with stage IIIA, pathologic N2 disease were randomized to either concurrent chemotherapy with cisplatin/etoposide and radiation to 4500 cGy followed by surgery or the same chemotherapy regimen with radiation to higher doses of 6100 cGy. The patients who were randomized to surgery had a statistically significant improvement in progression-free survival (12.8 vs. 10.5 months); although there was a trend toward an improvement in OS in the surgery group, this was not statistically significant. In an unplanned subset analysis, patients who seemed to do better were those who had a lobectomy rather than a pneumonectomy, as well as those who had obtained a pathologic response in the mediastinal nodes. Although there was no significant benefit in OS, surgery is often offered to medically fit patients after induction chemoradiotherapy.

■ Locally Advanced Inoperable or Unresectable Stage III NSCLC

Below are considered treatment approaches based on sequential or concurrent chemotherapy and radiation therapy to manage locally advanced, inoperable, or unresectable stage III NSCLC.

Chemotherapy Followed by Radiation Therapy

Several prospective, randomized studies have compared radiation therapy alone and radiation therapy in sequence with chemotherapy in the setting of unresectable stage III disease. Le Chevalier et al.[30] randomized 353 patients to radiation alone (6500 cGy) or cisplatin-based chemotherapy followed by radiation; 1-, 2- and 3-year survival rates all favored the combined therapy arm (51%, 21%, and 12% vs. 41%, 14%, and 4%, respectively). However, using repeat biopsies, the study found only a 17% incidence of local control in the radiation arm and a 15% incidence of local control in the chemotherapy and radiation arm.

In a trial conducted by CALGB, 155 patients were randomized to either radiation alone (6000 cGy) or a cisplatin-based regimen followed by radiation.[31] The median survival favored the combination therapy arm (13.8 vs. 9.7 months). The 3- and 5-year survival rates also favored combination therapy (25% and 19%) over radiation therapy alone (11% and 7%). Unfortunately, the study was limited to patients with a high performance status and less than 5% weight loss in the 6 months before enrollment in the trial. Limiting a study to the most favorable patients begs the question of the applicability of the results to the general group of patients with locally advanced lung cancer, many of whom have a decrease in their performance status and have lost considerable weight.

A study seeking to confirm the CALGB report was initiated by the Radiation Therapy Oncology Group (RTOG), which randomized patients to the same two arms, in addition to a third arm using hyperfractionation radiation (69.6-cGy twice-daily fractions) as the only treatment modality.[32] This study demonstrated that chemotherapy given prior to radiation was superior to radiation alone in the patients with good performance status (i.e., loss of weight of $<5\%$ in the previous 3 months). Analysis at 1 year showed the median survival to be statistically longer for those in the combined chemotherapy and radiation arm. However, at 3 years follow-up, no difference in survival (14%) was observed between the chemotherapy and radiation arm and the hyperfractionated arm. Both of these treatment regimens were better than standard radiation alone.

Concurrent Chemotherapy and Radiation Therapy

The rationale for concurrent therapy, that is, chemotherapy given during a course of radiation therapy, is based on the concept that some drugs or drug combinations (notably, cisplatin) may increase the radiosensitivity of tumor cells. However, the trade-off is an increase in toxicity and a regimen that is not well tolerated by all potentially eligible patients. A meta-analysis of randomized trials directly comparing platinum-based chemotherapy given concurrently with thoracic radiation to chemotherapy given sequentially with thoracic radiation was performed in 2010.[33] Data from 6 trials (1205 individual patients) were analyzed. There was a significant benefit to concurrent therapy with an absolute OS benefit of 5.7% at 3 years (HR, 0.84; 95% CI, 0.74–0.95; $p = 0.004$). The primary effect was seen in control of locoregional disease, with no difference in risk of distant recurrence compared to sequential therapy. The risk of severe esophagitis was increased with concurrent therapy, although pulmonary toxicity was not different. Concurrent platinum chemotherapy and radiation therapy is the treatment of choice for patients with locally advanced, inoperable disease, provided their performance status and comorbidities do not limit their ability to withstand the toxicities associated with this approach. Based on small phase 2 trials conducted by SWOG, a favored regimen for concurrent therapy utilizes cisplatin (days 1, 8, 29, 36) and etoposide (days 1–5, 29–33) with conventional RT.[28,34] For those patients unable to receive cisplatin due to renal insufficiency or hearing loss, weekly carboplatin and paclitaxel has demonstrated activity in this setting. The OS seen with carboplatin and paclitaxel treatment is less than the control arms of the cisplatin/etoposide studies, although these 2 chemotherapy regimens have not been directly compared in a randomized trial.

PROCLAIM is a phase 3 study of concurrent chemotherapy with radiation followed by two additional cycles of chemotherapy given in consolidation to those with unresectable NSCLC. In this study, patients were randomized to pemetrexed, cisplatin, and concurrent radiation with additional cycles of pemetrexed as consolidation or the standard regimen of cisplatin and etoposide with concurrent radiation and two additional cycles of cisplatin and etoposide as consolidation. This study attempted to improve upon the toxicity seen with the concurrent approach.[35] For patients with nonsquamous NSCLC, the use of pemetrexed did not improve overall survival. However, there was a significant decrease in grade 3 to 4 adverse events, including neutropenia. Thus, the NCCN has added this regimen to recommended chemotherapy for concurrent chemoradiation. For those unable to tolerate a concurrent approach, sequential chemotherapy followed by radiation is a reasonable alternative.

Induction or Consolidation Chemotherapy in Addition to Concurrent Chemoradiation

Although the addition of concurrent platinum-based chemotherapy to thoracic radiation for unresectable stage III NSCLC has been proven to improve local control and OS, disease recurrence at distant sites remains high. With concurrent therapy, only two cycles of chemotherapy are given during the course of radiation. This is fewer than the four cycles of cisplatin-based chemotherapy that has proven benefit to lessen disease recurrence in the adjuvant setting. This led to an interest in increasing the amount of chemotherapy given for patients receiving concurrent therapy in locally advanced disease by adding additional chemotherapy cycles either prior to (induction) or after (consolidation) the concurrent chemoradiation.

Multiple clinical trials have studied each of these approaches. In a nonrandomized phase 2 study, concurrent chemoradiation was followed by two cycles of consolidation cisplatin and etoposide, resulting in a median survival of 15 months and a 5-year survival of 15%.[34] A subsequent trial used the same combined treatment regimen but then switched to docetaxel for consolidation.[36] This yielded a median survival of 26 months and a 3-year survival of 37%. However, a randomized study performed by the Hoosier Oncology Group in which patients received cisplatin, etoposide, and radiation, either with or without consolidation docetaxel, failed to show a benefit from consolidation treatment.[37] Another favored regimen utilizes low-dose carboplatin and paclitaxel with radiation, followed by consolidation therapy with the same agents. Noncomparative phase 2 studies of this regimen demonstrated a median survival of 16 months.[38] CALGB published findings of a phase 3 randomized study of two cycles of induction chemotherapy with full-dose carboplatin and paclitaxel followed by concurrent weekly dosing with radiation versus concurrent therapy alone.[39] OS was not significantly improved with induction therapy (14 vs. 12 months; $p = 0.3$).

New Approaches to Concurrent Chemoradiation

Due to poor outcomes and limitations of adding further chemotherapy to locally advanced disease, a different approach was needed. A pivotal trial in improving the survival outcomes of these patients was the PACIFIC trial. This study of locally advanced, nonresectable NSCLC included a unique approach to consolidation with an immune checkpoint inhibitor. The PACIFIC trial is a randomized, phase 3 trial of consolidation with durvalumab (PD-L1 inhibitor) versus placebo following concurrent radiation and chemotherapy.[40] Patients who had no signs of disease progression following completion of thoracic radiation and at least 2 cycles of platinum-based chemotherapy were eligible for enrollment. A total of 713 patients underwent randomization to 12 months of durvalumab or placebo, with PFS and OS as coprimary endpoints. The median PFS from randomization was 16.8 months (95% CI, 13.0–18.1) with durvalumab versus 5.6 months (95% CI, 4.6–7.8) with placebo. The recently updated OS demonstrated an HR of 0.69 (95% CI, 0.55–0.86), with the median survival not reached for durvalumab (95% CI, 38.4 months to not reached) and 29.1 months (95% CI, 22.1–35.1) with placebo.[41] Thus, the addition of durvalumab as consolidative immunotherapy improved survival of patients undergoing concurrent, definitive chemoradiation. The PACIFIC trial has changed the standard of care for patients with unresectable, locally advanced NSCLC.

In summary, significant issues remain concerning the sequence and type of treatment for locally advanced disease. Although some permutation of combined modality treatment is needed in patients with locally advanced disease, we currently do not have data in the form of randomized controlled studies that compare the efficacy of the varying combinations of chemotherapy, immunotherapy, radiation, and surgery. In patients who can tolerate the added toxicity, concurrent chemoradiotherapy is more effective than sequential therapy. Although it has not been proven that surgery after induction chemoradiotherapy confers a survival benefit compared to definitive chemoradiotherapy, surgery is still a preferred approach in many institutions if patients can tolerate trimodality treatment. It remains unclear how definitive chemoradiotherapy compares to induction chemotherapy followed by surgery or chemoradiotherapy followed by surgery, particularly with the addition of immunotherapy. At the present time, this is a matter of institutional preference, as well as the particular characteristics of individual patients.

METASTATIC NSCLC

The first-line treatment for metastatic NSCLC has been redefined due to the introduction of immune checkpoint inhibitors and an increasing number of targeted agents for oncogenic drivers of disease. Currently, personalized treatment plans can be developed for each patient within several cohorts: (1) those with drug targeted driver mutations, (2) those with immune biomarkers predictive of durable response to single-agent PD-1 or PD-L1 inhibitors, (3) those who lack both and require a combination of chemotherapy with immunotherapy, and (4) those with contraindications to immunotherapy and who are treated with chemotherapy alone. Because the treatment of metastatic NSCLC is based upon driver mutations and immunotherapy biomarkers, prompt molecular testing of the tumor is of increasing importance. Currently, in addition to immune biomarkers for all NSCLC, the NCCN recommends testing all newly diagnosed nonsquamous-cell NSCLC (and all cell types in never-smokers) for an increasing number of activating mutations.[42] In metastatic lung cancer, the goals of therapy are to extend survival and to palliate the symptoms of disease. The decision to use cancer-directed therapy in the setting of incurable disease is based on patient preference, comorbidities, and performance status and requires an ongoing dialogue between the patient and physician throughout the disease course.

■ First-line Chemotherapy

Chemotherapy alone is recommended for those with metastatic NSCLC and contraindications to PD-1 or PD-L1 inhibitors, with no activating mutations in EGFR, ALK, c-ros oncogene 1 (ROS1), or the serine/threonine kinase B-raf (BRAF). For patients with adequate performance status, the standard first-line chemotherapy recommendations currently consist of a platinum doublet, with several reasonable nonplatinum combinations as alternatives. Although there are several cisplatin or carboplatin backbone doublets to consider, carboplatin tends to be favored in the palliative setting due to its better toxicity profile. A large study conducted by the ECOG randomized 1207 patients with advanced disease to cisplatin/paclitaxel, cisplatin/gemcitabine, cisplatin/docetaxel, or carboplatin/paclitaxel.[43] The median survival among all 4 treatment groups was 7.9 months, with a 1-year survival of 33% and a 2-year survival of 11%. There was no clear survival benefit with any one regimen compared with the others.

Pemetrexed, an antifolate, is a cytotoxic agent, unique in that efficacy varies by the histology of the NSCLC. It is labeled by the U.S. Food and Drug Administration for use in nonsquamous-cell NSCLC only. This labeling is based on a phase 3 trial in which newly diagnosed patients with advanced NSCLC were randomized to either cisplatin/gemcitabine or cisplatin/pemetrexed in the first-line setting.[44] This trial was designed as a noninferiority study and demonstrated that the cisplatin/pemetrexed doublet was noninferior to a standard doublet with a median OS of 10.3 months. When given with the appropriate folic acid and vitamin B12 supplementation, the cisplatin/pemetrexed doublet was associated with less cytopenia and decreased the need for growth factors and blood transfusions. A prespecified histology stratification was performed comparing nonsquamous NSCLC (including adenocarcinoma, large cell carcinoma, and others) versus squamous cell NSCLC. Median OS for the nonsquamous NSCLC histology was 11.0 months for those who received cisplatin/pemetrexed versus 10.1 months for cisplatin/gemcitabine (HR, 0.84; 95% CI, 0.74–0.96). However, for those with squamous cell histology, cisplatin/pemetrexed had an inferior median OS of 9.4 months versus 10.8 months with cisplatin/gemcitabine (HR, 1.22; 95% CI, 0.99–1.5). As pemetrexed is well tolerated and not associated with alopecia, carboplatin with pemetrexed is a widely used first-line regimen in nonsquamous cell NSCLC.

Albumin-bound paclitaxel (also called nab-paclitaxel) is a novel formulation with a reduced risk of hypersensitivity compared with other taxanes (paclitaxel and docetaxel). A large randomized study of carboplatin with either paclitaxel given every 3 weeks or nab-paclitaxel given weekly demonstrated an improved response rate with nab-paclitaxel (33% vs. 25%; $p = 0.005$) with less peripheral neuropathy.[45] No change in OS was noted among the different paclitaxel formulations: median OS 12.1 months versus 11.2 months

($p = 0.271$). The use of nab-paclitaxel with carboplatin is particularly useful in those with a history of hypersensitivity to docetaxel or paclitaxel or those with a contraindication to high-dose corticosteroids as premedication. Carboplatin and weekly nab-paclitaxel is an additional platinum-based doublet that can be used in the first line.

Two randomized phase 3 studies have addressed the use of non–platinum-based regimens as first-line treatment. The first randomized patients to paclitaxel and gemcitabine versus paclitaxel and carboplatin.[46] The study showed similar efficacy with respect to median survival, 1-year survival, and response rate. Both regimens were well tolerated. The largest study to address the role of nonplatinum doublets randomly allocated 929 patients to carboplatin/paclitaxel, carboplatin/gemcitabine, or gemcitabine/paclitaxel.[47] Again, the results indicated similar efficacy in all 3 arms. There were differences in toxicities in that anemia and thrombocytopenia were more common in the carboplatin/gemcitabine arm, although peripheral neuropathy and alopecia were more common in the paclitaxel containing groups. For chemotherapy-naïve patients, treatment choices tend to be heavily dependent on a patient's comorbidities and each regimen's toxicity profile.

The monoclonal antibody bevacizumab, which targets the vascular endothelial growth factor (VEGF), is approved for first-line treatment of NSCLC when combined with cytotoxic chemotherapy. VEGF, a circulating ligand that promotes angiogenesis, is not mutated in NSCLC, and this therapy, although molecularly targeted, is not specific to the tumor. A large randomized phase 3 study published in 2006 demonstrated an improvement in OS—12.3 versus 10.3 months (HR, 0.79; $p = 0.003$)—for those patients who received bevacizumab in addition to carboplatin and paclitaxel for advanced NSCLC.[48] Additional studies demonstrated equal efficacy when bevacizumab is combined with carboplatin and pemetrexed.[49] Due to the high risk of life-threatening hemoptysis seen in early clinical trials, patients with squamous-cell lung cancer or a history of hemoptysis were excluded from this study. As an antiangiogenesis agent, bevacizumab has several unique adverse effects, including hemoptysis, hypertension, and proteinuria.[50] When carefully used in patients with advanced lung cancer, bevacizumab is a novel targeted agent that can improve survival.

■ Immunotherapy as First-line Therapy

The biggest impact of immunotherapy in NSCLC has been in the metastatic setting. Clinical trials have shown significant improvement in PFS and OS with a combination of cytotoxic chemotherapy and an anti PD-1 or PD-L1 monoclonal antibody. This improvement has been observed in multiple studies independent of histology, and across all levels of PD-L1 expression[51] (Table 114-2). Immunotherapy is often well tolerated and able to produce a durable response. Therefore, immune checkpoint inhibitors are continued as maintenance therapy providing a subset of patients benefit over long periods. The development of immunotherapy biomarkers identifies patients predicted to have high objective response rates and PFS with the use of immune checkpoint inhibitors as a single agent, thus reducing the toxicity of adding cytotoxic chemotherapy in the first line. To date, validated biomarkers in this setting include PD-L1 expression by IHC staining of tumor cells and tumor mutational burden, a standardized number of somatic mutations within the tumor.

TABLE 114-2 Randomized Trials of Immune Checkpoint Inhibitors in First-line Treatment of Advanced NSCLC

Clinical Trial	Histology	PD-L1 TPS	Treatment	Median PFS	Median OS
Keynote 042[51]	NSCLC (EGFR and ALK neg)	≥1%	Pembrolizumab	5.4	16.7
			Chemotherapy	6.5	12.1
Keynote 189[52,53]	Nonsquamous NSCLC (EGFR and ALK neg)	0%–100%	Pembrolizumab and pemetrexed with carbo/cisplatin	9.0	22.0
			Pemetrexed with carbo/cisplatin	4.9	10.7
Keynote 024[56,57]	NSCLC (EGFR and ALK neg)	≥50%	Pembrolizumab	10.3	30.0
			Chemotherapy	6.0	14.2
Keynote 407[55]	Squamous cell carcinoma	0%–100%	Pembrolizumab and (nab) paclitaxel with carboplatin	6.4	15.9
			(nab) Paclitaxel with carboplatin	4.8	11.3
Checkmate 227[59]	NSCLC (EGFR and ALK neg)	≥1%	Nivolumab and ipilimumab	5.1	17.1
			Nivolumab	4.2	15.7
			Chemotherapy	5.6	14.9
IMpower 110[58]	NSCLC	TC 3 or IC 3 (TC1/2/3 or IC1/2/3)	Atezolizumab		20.2 (17.5)
			Chemotherapy		13.1 (14.1)
IMpower 130[54]	Nonsquamous NSCLC (EGFR and ALK neg)	0%–100%	Atezolizumab and carboplatin with (nab) paclitaxel	7.0	18.6
			Carboplatin with (nab) paclitaxel	5.5	13.9
IMpower 150[60]	Nonsquamous NSCLC (EGFR and ALK neg)	0%–100%	Atezolizumab and carboplatin/paclitaxel and bevacizumab	8.3	19.2
			Carboplatin/paclitaxel and bevacizumab	6.8	14.7

PD-L1 TPS, programmed death ligand 1 tumor proportion score; PFS, progression-free survival; OS, overall survival; NSCLC, non–small-cell lung cancer; EGFR, epidermal growth factor receptor; ALK, anaplastic lymphoma kinase; TC, tumor cells; IC, tumor-infiltrating immune cells.

The current recommendation for patients with newly diagnosed, metastatic, nonsquamous NSCLC is a combination of PD-1 or PD-L1 inhibitor with a carboplatin-based doublet. This recommendation is based on 2 large, randomized studies, Keynote-189 and IMpower130. Both studies enrolled patients without an activating mutation in EGFR or ALK. The Keynote-189 study enrolled 616 patients randomized to carboplatin or cisplatin and pemetrexed with or without pembrolizumab (PD-L1 inhibitor).[52] Combined therapy was given for 4 cycles, followed by maintenance therapy with either pemetrexed alone or combined with pembrolizumab. The median PFS was 9.0 months (95% CI, 8.1–9.9) in the pembrolizumab group versus 4.9 months (95% CI, 4.7–5.5) in the placebo group. HR for death or disease progression was 0.48 (95% CI, 0.40–0.58; $p < 0.001$). Median OS was 22.0 months (95% CI, 19.5–25.2) in the pembrolizumab combined group versus 10.7 months (95% CI, 8.7–13.6) with HR of 0.56 (95% CI, 0.45–0.70).[53] This benefit was seen across all levels of PD-L1 expression, including <1%. The IMpower130 study had a similar design with 723 patients randomized to carboplatin and nab-paclitaxel (given weekly) plus atezolizumab (PD-L1 inhibitor) or placebo.[54] Combined therapy was given for 4 to 6 cycles followed by maintenance atezolizumab or placebo if no progression was seen. Median PFS was 7.0 months with atezolizumab (95% CI, 6.2–7.3) versus 5.5 months (95% CI, 4.4–5.9) with HR of 0.64 ($p < 0.001$), and median OS was 18.6 months (95% CI, 16.0–21.2) versus 13.9 months (95% CI, 12.0–18.7) with HR of 0.79 ($p = 0.033$). In both studies, the combined therapy was well tolerated.

Keynote-407 investigated a combined chemotherapy and immunotherapy approach in 599 patients with advanced squamous-cell carcinoma, regardless of PD-L1 expression level.[55] Again, pembrolizumab or placebo was added to a combination of carboplatin and either paclitaxel or nab-paclitaxel. The combination was given for 4 cycles with maintenance pembrolizumab or placebo for those without disease progression. The median PFS was 6.4 months with pembrolizumab (95% CI, 6.2–8.3) versus 4.8 months (95% CI, 4.3–5.7) with HR of 0.56 ($p < 0.001$). Median OS was 15.9 months (95% CI, 13.2–NR) in those with pembrolizumab versus 11.3 months (95% CI, 9.5–14.8) with placebo, with HR of 0.64 ($p < 0.001$). Thus, a combination of chemotherapy with an immune checkpoint inhibitor is now recommended first-line treatment for all histologic types of metastatic NSCLC.

The development of PD-L1 expression as a biomarker is most useful in determining if single-agent immune checkpoint inhibitors will produce a high response rate and PFS for individual patients, without the need to combine with chemotherapy. The Keynote-024 study was designed to determine if patients with newly diagnosed, advanced NSCLC and high PD-L1 tumor expression (PD-L1 expression on ≥50% of tumor cells), without an activating mutation in EGFR or ALK, would benefit from pembrolizumab alone. A total of 305 patients were randomized to pembrolizumab alone versus platinum-based chemotherapy. This study demonstrated that those with high PD-L1 expression had an improved PFS and OS with fewer adverse effects when given pembrolizumab alone in the first line compared to chemotherapy.[56] At 25 months of follow-up, the OS for pembrolizumab was 30 months (95% CI, 18.3–NR) versus 14.2 months for chemotherapy alone (95% CI, 9.8–19), with HR of 0.63 (95% CI, 0.47–0.86).[57] This improvement in OS was seen despite a high rate of crossover from the chemotherapy group to pembrolizumab upon progression. Subsequent studies have shown similar efficacy with other immune checkpoint inhibitors (atezolizumab) in this select group.[58] At this time, there are no data directly comparing immune checkpoint inhibitors alone to combined therapy for those with high PD-L1 expression. In patients with a large tumor burden or suffering complications of disease, a combination of chemotherapy and immunotherapy may provide faster disease response and may be necessary even in the setting of high PD-L1 expression.

Another approach to first-line therapy is the combination of different immunotherapies without the addition of chemotherapy. In Checkmate-227, patients were randomized to chemotherapy alone or a combination of nivolumab (a PD-L1 inhibitor) with ipilimumab (a cytotoxic T-lymphocyte–associated protein 4 [CTLA-4] inhibitor).[59] In those with PD-L1 expression ≥1%, the combination of nivolumab and ipilimumab produced a longer OS than chemotherapy alone—17.1 months (95% CI, 15.0–20.1) versus 14.9 months (95% CI, 12.7–16.7). This combination provides an alternative first-line therapy to the use of cytotoxic chemotherapy.

Nearly all of the first-line studies of immunotherapy alone or in combination with chemotherapy have excluded those with EGFR-activating mutations or translocations in ALK. Early studies of immune checkpoint inhibitors in the second line showed a low response rate to immunotherapy in these patients, despite PD-L1 expression on tumor cells. This led to a question of the appropriate therapy for these patients once resistance to targeted agents has developed. The current recommendations are for chemotherapy alone or combined with bevacizumab. The IMpower150 study enrolled patients with known EGFR mutations into a randomized trial of three arms: chemotherapy with bevacizumab, chemotherapy with atezolizumab, or a combination of chemotherapy with bevacizumab and atezolizumab. A total of 1202 patients were enrolled; 124 had known EGFR mutations. Analysis of the EGFR-mutated subgroup showed a trend toward improved OS with the combination of immunotherapy, chemotherapy, and bevacizumab compared to chemotherapy and bevacizumab alone (HR, 0.31; 95% CI, 0.11–0.83).[60] The authors believed this warranted further study of this immunotherapy combination in EGFR-mutated disease.

The introduction and now widespread use of immune checkpoint inhibitors in the treatment of advanced NSCLC has required that clinicians recognize and manage immune-related adverse events. These adverse events are often distinct from those associated with cytotoxic chemotherapy and may involve a wide range of organ systems. Commonly these are low-grade adverse events involving the skin, thyroid, and GI tract. However, moderate to severe adverse events—for example, pneumonitis or hepatitis—may develop, requiring permanent discontinuation of immune therapy and prompt treatment with corticosteroids and additional immunosuppressive agents.[61] The use of immune therapy in those with a history of autoimmune disease is particularly high-risk, and careful consideration and discussion with the patient is needed prior to use.

■ Elderly Patients with Advanced NSCLC

The median age at diagnosis for patients with NSCLC is 65 years; therefore, a significant number of patients diagnosed with advanced disease are elderly (≥70 years). Chemotherapy has been demonstrated to improve survival in the elderly with advanced disease to the same extent as those who are young.[62] Although there is an increase in side effects, particularly cytopenias, advanced age is not a contraindication to chemotherapy. Randomized studies dedicated to the treatment of elderly patients with advanced NSCLC are few, but several have provided needed data for this group. A randomized trial using a carboplatin-based doublet for elderly patients randomized patients to single-agent vinorelbine or gemcitabine versus carboplatin and weekly paclitaxel.[63] Those who received the platinum-based doublet had a higher response rate (27% vs. 10.2%; $p < 0.0001$) and better OS (10.3 vs. 6.2 months; $p < 0.001$). Higher rates of febrile neutropenia were seen with the doublet therapy. This study supports the use of carboplatin and weekly paclitaxel in elderly patients with good performance status with close monitoring for associated cytopenia. More recent clinical trials of immunotherapy in advanced NSCLC have removed exclusions based on age. These studies have enrolled significant subpopulations of patients ≥75 years of age with good performance status. Outcomes in this older population of fit patients are consistent with that seen in the overall population.

Patients with Poor Performance Status

Patients with poor performance status represent another common group in need of treatment for advanced lung cancer but are underrepresented in randomized clinical trials. Patients with ECOG performance status grade 2—defined as "ambulatory and capable of all self-care but unable to carry out any work activities; up and about more than 50% of waking hours"—if included in first-line trials, represent a small proportion of those enrolled. A randomized clinical trial dedicated to first-line treatment of patients with ECOG performance status grade 2 randomized patients to pemetrexed alone versus carboplatin and pemetrexed.[64] Those who received the platinum-based doublet had an improved response rate (24% vs. 20%) and improved median OS (9.1 vs. 5.6 months; $p = 0.001$). For those patients with ECOG performance status grade 3—"capable of only limited self-care, confined to a bed or chair more than 50% of waking hours"—cytotoxic chemotherapy is of no known benefit, and best supportive care is recommended. Unfortunately, modern studies of immunotherapy, including those described above, routinely exclude patients with an ECOG performance status grade 2, leaving a gap of knowledge in the best first-line therapy for this group of patients.

Maintenance Therapy for Advanced Disease

Historically, first-line chemotherapy for NSCLC was given for four to six cycles and then held, as there was no proven benefit to extending treatment with a doublet past six cycles. If the disease was under control (responded to therapy or stable), all treatment was held, and the patient was followed clinically until disease progression. At that time, the patient would be considered for second-line chemotherapy. The availability of drugs that are better tolerated, such as pemetrexed and immune checkpoint inhibitors, has enabled investigators to reevaluate this approach and consider maintenance therapy for those with disease control following first-line treatment. Maintenance therapy is given to keep cancer from progressing after response to initial treatment. Recent clinical studies have demonstrated an OS benefit with the use of maintenance therapy, and it has become the standard of care in advanced NSCLC treatment.

Continuation maintenance is "the use of at least one of the agents given in the first line, beyond four to six cycles, in the absence of disease progression."[42] Several agents originally approved for use in the first line have been used in this fashion. For example, all studies of first-line immune checkpoint inhibitors continue the immunotherapy as maintenance until disease progression or serious adverse event. In clinical trial ECOG 4599, bevacizumab was continued until disease progression even after the carboplatin and paclitaxel were held after four to six cycles. Pemetrexed also has been studied as a single agent given as continuous maintenance therapy when used as part of a platinum-based doublet in the first line.[65] PARAMOUNT, a randomized trial of continuous maintenance pemetrexed following first-line treatment with cisplatin/pemetrexed, demonstrated an improvement in progression-free survival when compared with placebo: 4.1 months versus 2.8 months ($p < 0.001$) after randomization.[66] There are also data to suggest an OS advantage to the continuous use of pemetrexed (13.9 vs. 11.0 months).[67] As a result, the current recommendation in those with disease control following cisplatin (or carboplatin) with pemetrexed is to continue pemetrexed until disease progression. In a similar design, the clinical trial AVAPERL randomized patients to bevacizumab/pemetrexed versus bevacizumab alone as continuous maintenance following disease response to first-line cisplatin, pemetrexed, and bevacizumab. Data from this trial showed that the use of pemetrexed and bevacizumab together in the maintenance setting was associated with superior PFS (10.2 vs. 6.6 months; HR, 0.58; $p < 0.001$) and a trend toward improved OS (17.1 vs. 13.2 months; HR, 0.87; $p = 0.32$).[68] Thus, when disease response is seen with cisplatin, pemetrexed, and bevacizumab in the first line, consideration for continuation with pemetrexed and bevacizumab is recommended. POINTBREAK, an open-label, randomized, phase 3 study comparing carboplatin, paclitaxel, and bevacizumab with bevacizumab as maintenance to carboplatin, pemetrexed, and bevacizumab with bevacizumab and pemetrexed as maintenance found no difference in OS.[49] Due to less toxicity associated with the carboplatin, pemetrexed, and bevacizumab therapy, this is the preferred regimen for those with nonsquamous-cell NSCLC.

As previously described, due to increased risk of hemoptysis with bevacizumab, and decreased efficacy with pemetrexed, patients with squamous-cell NSCLC are not able to receive these drugs as maintenance therapy. A clinical study with a significant number of patients with squamous-cell NSCLC investigated the use of gemcitabine as continuous maintenance following cisplatin/gemcitabine induction chemotherapy.[69] Progression-free survival was significantly improved in those who received gemcitabine versus placebo following induction chemotherapy. An overall survival benefit was seen in those who received gemcitabine after an objective response to induction therapy, but not those with stable disease. This suggests that gemcitabine is a reasonable agent to use as continuous maintenance in patients with squamous-cell carcinoma with response to platinum-gemcitabine in the first line.

Second-line Therapy

Ultimately, patients with advanced disease will progress after receiving first-line therapy, with or without maintenance treatment. There are several options to consider in the second-line setting, and the selection of the appropriate agent depends on histology, ECOG performance status, and previous treatment. Docetaxel was one of the first agents approved for this indication. In the first trial of interest, 104 previously treated patients were randomized to docetaxel every 3 weeks at 100 mg/m^2, 75 mg/m^2, or supportive care.[70] Docetaxel therapy improved median survival (7.5 vs. 4.6 months) and 1-year survival (37% vs. 11%). The lower dose of docetaxel was better tolerated. Further improvement in second-line therapy has been studied with drugs in combination with docetaxel. The REVEL study investigated the addition of ramucirumab, a monoclonal antibody that inhibits VEGF receptors, to docetaxel in the second line, regardless of histology. Median OS was longer in those who received ramucirumab with docetaxel, 10.5 months versus 9.1 months, with HR of 0.86 (95% CI, 0.75–0.98; $p < 0.023$).[71] However, patients in this study had a high rate of serious adverse events (>70%) in both the control arm of docetaxel and with the ramucirumab combination. Due to the high incidence of adverse events, the administration of docetaxel in second-line NSCLC requires careful follow-up and supportive care.

In a phase 3 trial of pemetrexed in NSCLC, 571 patients were randomized to docetaxel or pemetrexed in the second-line setting.[72] Survival was similar in each arm with a median survival of 8.3 and 7.9 months for pemetrexed and docetaxel, respectively. The 1-year survival was 29.7% in both groups. Although survival with pemetrexed was not improved compared to docetaxel alone, pemetrexed was better tolerated with a significant decrease in the incidence of grade 3 or 4 neutropenia and febrile neutropenia events.

The majority of patients with advanced NSCLC receive immunotherapy in the first line, either as a single agent or combined with chemotherapy. For those who did not receive an immune checkpoint inhibitor in the first line, multiple studies have demonstrated improved outcomes for single-agent immune checkpoint inhibition therapy compared to docetaxel. Nivolumab and atezolizumab have been approved for use regardless of PD-L1 expression level, while pembrolizumab is recommended for those with PD-L1 ≥1% based on the Keynote-010 study.[73] In this randomized study, patients previously treated for NSCLC and known PD-L1 $\geq 1\%$ were randomized to pembrolizumab (at two different dosing levels: 2 mg/kg and 10 mg/kg) versus docetaxel. The median overall survival was 10.4 months with pembrolizumab 2 mg/kg, 12.7 months with pembrolizumab 10 mg/kg, and 8.5 months with docetaxel. Each pembrolizumab arm had a significant prolongation of overall survival compared to docetaxel. Notably, serious treatment-related adverse events are less common with immune checkpoint inhibitors than docetaxel in the second line.

■ Molecular Targeted Therapy

Advances in molecular biology have enabled the search for novel molecular abnormalities in lung cancer that provide insights into tumorigenesis as well as potential therapeutic targets. The identification of "driver mutations," those mutations that drive neoplastic transformation and contribute to tumor progression, has accelerated and led to multiple recent drug approvals for targeted therapy in advanced NSCLC (Table 114-3). As the identification of driver mutations significantly impacts the selection of first-line therapy, thorough and timely molecular testing is of growing importance. Due to the small tissue samples often obtained in NSCLC, acquiring sufficient material for extensive histologic and molecular testing often requires a repeat biopsy, further delaying treatment. The use of circulating tumor DNA testing (liquid biopsy) can aid in the detection of driver mutations when the tissue sample is insufficient or the patient is too high-risk to undergo a diagnostic procedure. Although the specificity of a liquid biopsy assay is high, the sensitivity remains low. Thus, a tissue biopsy should be used for molecular testing whenever possible.[42] Current recommendations are for molecular testing in all patients with adenocarcinoma, adenosquamous carcinoma, a small biopsy sample, or limited smoking history. In addition to IHC for PD-L1 expression, the current recommended testing includes EGFR mutations, ALK genes fusions, ROS1 gene fusions, BRAF V600E mutations, ret proto-oncogene (RET) rearrangements, hepatocyte growth factor receptor (MET) exon 14 skipping mutations, and neurotrophic tyrosine receptor kinase (NTRK) gene fusions. As the advancement in targeted therapy of NSCLC continues, the number of biomarkers is expanding. A broad panel of next-generation sequencing (NGS) is often used to ensure that all molecular variants are identified.

EGFR was the first driver mutation to introduce personalized medicine for NSCLC. It was also the first to demonstrate improved outcomes for a TKI over chemotherapy in the first-line treatment of advanced adenocarcinoma.[74] EGFR mutations have been reported in 10% to 15% of Western and 25% to 30% of Asian lung cancer patients. These mutations are significantly more common in women and nonsmokers. Current testing should include molecular techniques to identify activating mutations in EGFR exons 18 to 21. This includes high-frequency L858R point mutations, exon 19 deletions, and less common mutations with at least 1% prevalence.[75] The presence of an activating EGFR mutation strongly predicts response to TKI therapy. There are now three generations of EGFR TKIs available for clinical use. First-generation TKIs bind reversibly to the kinase and include erlotinib and gefitinib. Second-generation TKIs bind irreversibly and include afatinib and dacomitinib. Finally, third-generation TKIs also bind irreversibly with additional activity against the T790M mutation; osimertinib is one example. The recommended first-line treatment for advanced, EGFR-mutated NSCLC is osimertinib, based on the phase 3 FLAURA trial. This clinical trial randomized previously untreated patients with EGFR-mutated NSCLC to osimertinib versus a first-generation EGFR TKI (either gefitinib or erlotinib). Osimertinib had a superior median PFS of 18.9 months compared to 10.2 months for first-generation inhibitors (HR, 0.46; 95% CI, 0.37–0.57; $p < 0.0001$).[76] Upon further follow-up, median OS was also superior with osimertinib: 38.6 months versus 31.8 months (HR, 0.80; 95% CI, 0.64–1.0; $p = 0.46$).[4] This improvement was attributed to improved control

TABLE 114-3 Targeted Therapy in Advanced Non–Small-Cell Lung Cancer

Molecular Target	Genetic Alteration	First-line Therapy	Subsequent Therapy	Reference
EGFR epidermal growth factor receptor	L858R/exon 19del[a]	Osimertinib,[b] erlotinib, gefitinib, afatinib, or dacomitinib	Osimertinib[b] if T790M mutation identified	76 80–84
	T790M	Osimertinib

of CNS metastatic disease, fewer serious adverse events leading to dose reduction, and expanded coverage of the T790M resistance mutation with osimertinib. Unfortunately, several EGFR mutations are associated with resistance to TKI treatment, for example, exon 20 insertions. Over time, almost all TKI-responsive lung cancers acquire secondary mutations rendering them resistant to further treatment and relapse is inevitable.[44] Mechanisms of resistance are being studied to provide future targeted therapy in this setting.

Another clinically relevant molecular subset of NSCLC is driven by the echinoderm microtubule–associated protein-like 4 (EML4) and ALK translocation.[49] The EML4–ALK translocation in NSCLC leads to the constitutive activation of the ALK kinase domain and promotes cell growth and survival. More recently, additional fusion partners have been identified with ALK. ALK translocations are found in approximately 2% to 5% of NSCLC, most commonly in never-smokers or light smokers with adenocarcinomas. The preferred first-line therapy for ALK-translocated, advanced NSCLC is the second-generation TKI alectinib. The recommendation is based on a phase 3 randomized trial, ALEX, of alectinib versus crizotinib, a first-generation TKI approved for treatment of ALK-mutated NSCLC. In this large trial of first-line treatment, alectinib had an improved median PFS of 34.8 months vs. 10.9 months (HR, 0.43; 95% CI, 0.32–0.58).[77,78] Alectinib had superior CNS control, fewer severe adverse events, and higher response rates. Several other second-generation ALK TKIs are approved for first-line therapy (brigatinib and ceritinib). Lorlatinib, a third-generation ALK inhibitor, has been shown to have activity in ALK-translocated NSCLC that has become resistant to previous ALK TKIs.[79] It is now recommended as a subsequent treatment for patients with resistance to previous ALK TKIs and is being studied as first-line treatment (Figs. 114-2 and 114-3).

EGFR mutations and ALK translocations are the most common driver mutations found in advanced NSCLC. However, multiple additional mutations have been identified and targeted as therapy. Current guidelines include recommendations for targeted therapy for the following driver mutations: ROS1 rearrangements, BRAF V600E mutations, NTRK fusions, MET 14 exon skipping mutations, and RET rearrangements. This list continues to expand as studies of targeted therapy for EGFR exon 20 insertions, KRAS G12C mutations, and HER2 amplifications are ongoing. Remarkable advances have been made in using oral targeted agents to treat advanced NSCLC with driver mutations. These include (1) broadening the number of unique driver mutations identified and treated with novel targeted agents, (2) expanding treatment of TKI-resistant disease to second-line therapies, and (3) improving agents used in the first line for previous targets (such as EGFR and ALK). Advances in targeted therapy have had a large impact on survival and quality of life for patients with advanced disease.

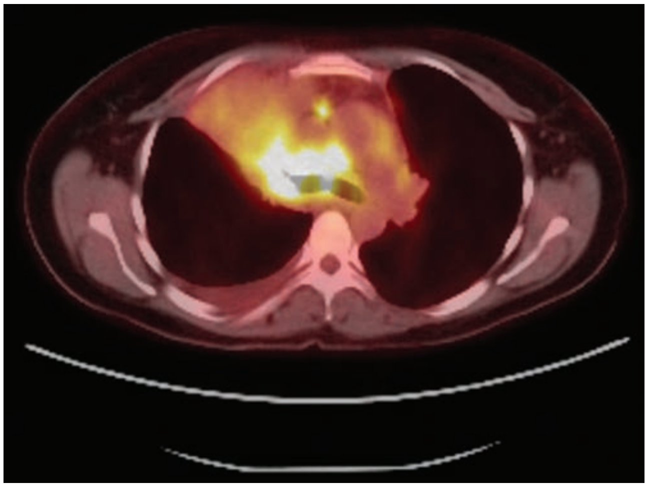

Figure 114-2 CT scan combined with fluorodeoxyglucose positron emission scan (FDG-PET) of a newly diagnosed metastatic lung adenocarcinoma in a never-smoker. This tumor was found to have an echinoderm microtubule–associated protein-like 4 (EML4) and anaplastic lymphoma kinase (ALK) translocation upon fluorescence in situ hybridization (FISH) analysis.

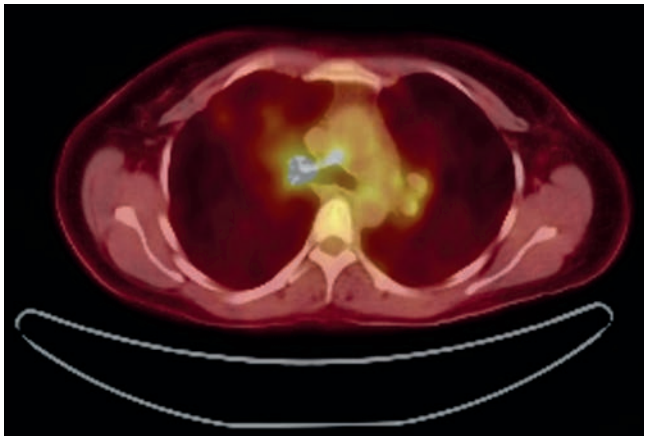

Figure 114-3 CT/FDG-PET scan of the same patient after 3 months of treatment with crizotinib, an oral tyrosine kinase inhibitor. The imaging shows marked disease response.

CONCLUSION

Chemotherapy has an established role in the adjuvant therapy of stage II and IIIA NSCLC. Randomized clinical trial data demonstrate improved median and long-term survival when antineoplastic agents are used with surgical resection. The next step in the development of adjuvant regimens will integrate molecular targeted agents and immunotherapy. These trials are already underway and showing promise. Multimodality therapy is necessary to treat locally advanced disease. The role of systemic treatment with chemotherapy and immunotherapy is essential to improve survival rates of those treated with radiation and surgery. Questions that need to be addressed in future and ongoing trials include the optimal sequence for various modalities in locally advanced disease as determined by biomarkers. For advanced-stage NSCLC, there is now a growing list of active agents. For those treated with targeted therapy for specific driver mutations or immunotherapy for high PD-L1 expression, remarkable advances in the durability of disease control have been seen. Further clinical studies are eagerly awaited with novel classes of immunotherapy beyond PD-L1, PD-1, and CTLA-4 inhibitors. However, there is still considerable room for improvement, particularly in those with poor performance status and heavily pretreated patients. Cost/benefit analysis is another consideration, as the newer agents are especially expensive. With the development of novel therapeutic agents and the future potential to select treatment options based on genomic and proteomic profiles, there is renewed optimism that the treatment of NSCLC will continue to improve in the future.

CHAPTER 115

Treatment of Non–Small-Cell Lung Cancer: Radiation Therapy

Joseph A. Miccio
Mitchell Machtay

We acknowledge the contributions of Ms. Barbara Husic in the administrative preparation of this chapter.

INTRODUCTION

Approximately 85% of lung cancers are non-small cell lung cancers (NSCLC), a heterogeneous group that is further divided into squamous cell and adenocarcinoma, the latter of which has numerous clinicopathologic–biologic subtypes. Unlike the situation for systemic treatment of NSCLC, presently, radiotherapy (RT) management differs very little among the various subtypes. It is anticipated that this will change in the future, as clinically useful predictive biomarkers for RT emerge but currently, and disappointingly, they do not yet exist. Conversely, however, this means that RT is a predictable, highly broad-spectrum agent against NSCLC. Most NSCLC patients receive RT at some point in the course of their illness; this may be thoracic RT and/or RT against metastatic sites, including though not limited to brain or bone metastases. Thoracic RT can be used for one of three treatment indications: (1) Definitive: An attempt at cure without surgery, using radiation as the primary local modality. (2) Palliative: Efforts directed toward short-term and/or long-term relief of cancer-related symptoms. (3) (Neo)-adjuvant: The integration of radiation prior to (neoadjuvant) or after (adjuvant) surgery, to improve the chance for permanent locoregional control.

There can be considerable overlap among these categories, and goals of treatment may change based on the patient's trajectory and disease course. A major example of this is the evolutionary use of stereotactic RT for patients with selected (oligometastatic or oligoprogressive) stage IV NSCLC who are doing well with systemic therapy; we describe this is as a hybrid between definitive and palliative treatment. Table 115-1 summarizes the different types of RT for lung cancer, with the typical associated radiation doses, treatment time, and other considerations.

The decision to use thoracic RT should usually occur in a multidisciplinary "tumor board" process in order to optimize integration of RT with other modalities. The factors most important in determining RT utilization are cancer stage and tumor size, along with the patient's pulmonary reserve and performance status. Consideration must also be given to psychosocial and logistic factors, such as the ability of the patient to cooperate with RT planning, delivery, and follow-up care. Table 115-2 illustrates the general (strong relative) contraindications to definitive intent thoracic RT.

Although there have been tremendous advances in the quality and safety of thoracic RT and multimodality treatment of lung cancer, it must be remembered that most NSCLC patients referred for RT have a poor prognosis for 5-year survival with standard-of-care therapy. As a result, consideration should be given to encouraging appropriate patients to participate in clinical trials.

DEFINITIVE RT FOR LOCALLY ADVANCED (INOPERABLE, BUT NONMETASTATIC) NSCLC

Patients without demonstrable distant metastases after thorough workup but who have locally advanced disease that precludes surgery are usually candidates for definitive RT. This includes most patients with stage III NSCLC and some stage II NSCLC. Workup

TABLE 115-1 Summary of Radiotherapy for NSCLC

Type	Stage/ Indication	Typical Radiation Dose	Radiation Time Course	Integration of Other Therapy	Comments
Definitive medically inoperable early stage	Stage I (and select stage II T3N0)	45–60 Gy	1–2 weeks	None	Stereotactic technology with ultra-accelerated fractionation
Definitive inoperable/ locally advanced	Stage III (and select stage II)	60–66 Gy	6–6.5 weeks	Concurrent chemotherapy and post-RT durvalumab	Pts not suitable for systemic therapy may be considered for moderately hypofractionated RT alone
Preoperative/ neoadjuvant	Select stage IIIA and Pancoast	45 Gy	5 weeks	Concurrent chemotherapy	
Postoperative/ adjuvant	Select stage IIIA	50 Gy (60 Gy if gross residual disease)	5 weeks	Start systemic therapy before adjuvant RT	
Palliative	Stage IV; select stage III	20–45 Gy	2–3 weeks	Systemic therapy as appropriate	Concurrent immunotherapy is OK, but generally not chemotherapy
Oligometastatic (quasi-definitive)	Select stage IV	30 to 60 Gy (stereotactic ultra-accelerated RT)	1–2 weeks	Systemic therapy as appropriate	Stereotactic technology with ultra-accelerated fractionation

TABLE 115-2 Relative Contraindications to Definitive (Curative Intent) RT for Lung Cancer

Contraindication(s)	Comments
Prior high-dose RT with field overlap	Length of time since previous RT and anatomic location of field overlap are important considerations when considering reirradiation
Autoimmune/active connective tissue disease and/or idiopathic pulmonary fibrosis (IPF)	
FEV_1 <800 cc	FEV_1 (or other PFTs) are generally not a contraindication to SBRT for peripheral stage I lung cancer
Tracheobronchial–esophageal fistula	
Tumor size/geometry so extensive that RT fields will include >37% of the patient's normal lung parenchyma, even with maximal technology RT	Generally analyzed as V20 (percent of total lung receiving 20 or more Gy); consider reduction in total prescribed RT dose and/or reduced treatment margins
Tumor size/geometry so extensive that RT fields will include >50% of the patient's heart/pericardium, even with maximal technology RT	Generally analyzed as V30 (percent of total heart receiving 30 or more Gy); consider reduction in total prescribed RT dose
Performance status (Zubrod) of 3 or 4	
Anticipated noncompliance with treatment or follow-up	It is important not to be "biased" in making this highly subjective judgment to deny someone potentially curative therapy

should include chest CT scan, FDG-PET/CT scan, brain MRI, and cytology of pleural effusion (if present). In many cases, pathologic staging of lymph nodes via endobronchial ultrasound (EBUS), endoesophageal ultrasound (EUS), or mediastinoscopy is appropriate before RT.

For patients who are medically fit, the current standard of care is a complex multimodality therapy regimen consisting of concurrent radiotherapy and chemotherapy (CCRT), followed by maintenance immunotherapy. (As of the writing of this chapter, the only FDA-approved immunotherapeutic for this purpose is durvalumab.)[1,2] Suitability for CCRT requires a Zubrod performance status of 0 or 1 (roughly corresponding to Karnofsky score of 70 or above). Significant weight loss is a relative contraindication based upon historic clinical trials showing this to be a poor prognostic factor.[3] Relatively advanced age is not an absolute contraindication for this approach,[4] although it should be noted that the pivotal clinical trials establishing the treatment have a median age of about 60 and few patients greater than or equal to 75 years old.

The conventional dose/fractionation schedule for definitive RT as part of CCRT is typically 60 Gy in standard fractionation (2 Gy once daily × 30 fractions over 6 weeks). A major randomized trial comparing 60 Gy/6 weeks with 74 Gy/7.4 weeks, with all patients receiving concurrent systemic therapy, not only failed to show benefit from the more intensive RT dose but demonstrated *worse* survival with 74 Gy.[5] It is hypothesized that toxicity (cardiopulmonary and/or immunologic) led to this paradoxical outcome. A secondary analysis of the trial suggested that patients treated with intensity-modulated radiation therapy (IMRT) had improved outcomes compared with "standard" conformal RT.[6] It is uncertain whether next-generation IMRT and/or proton beam RT with modestly intensified RT dose will perform better in newer trials. When patients are treated with RT alone for inoperable NSCLC, RT dose intensification may be more effective than standard 60 Gy/6-week therapy; this is important to keep in mind for patients who are not candidates for chemotherapy.[7]

The most commonly used CCRT regimen consists of weekly concurrent carboplatin/paclitaxel, although other regimens that combine a platinum (cisplatin or carboplatin) with a second agent such as etoposide, vinorelbine, docetaxel, or (for nonsquamous disease) pemetrexed also are well accepted. There are no conclusive studies showing an advantage (or major disadvantage) to any one of these platinum-based doublet regimens. There does not appear to be benefit from continuing chemotherapy after RT is completed.

The benefit from consolidation durvalumab was demonstrated in the PACIFIC trial to be strikingly positive (Fig. 115-1), and secondary analyses suggested that (1) a shorter interval between the completion of RT and the start of durvalumab was better; and (2) patients whose tumors were enriched in high levels of PDL1 had greater benefit.[1,2] It should be noted that the study only enrolled patients who were doing well after CCRT, without any major pulmonary toxicity and with no evidence of early disease progression.

The topic of pulmonary toxicity from RT is discussed later in this chapter. The transition from "large field" thoracic RT (i.e., fields that include the tumor plus elective nodal stations) to "involved field" RT lessened the risk and intensity of high-grade radiation pneumonopathy. Furthermore, this reduction in radiation field size has not negatively impacted survival.[8,9,] Current standard of care for most patients is to identify the gross tumor volume based on high-resolution and up-to-date imaging (CT, FDG-PET/CDT) and other data (e.g., results of EBUS when performed) and to limit the size of the RT fields. Figure 115-2 displays an example of a patient with stage III lung cancer treated with definitive chemoradiotherapy. Figure 115-3 illustrates the dose–volume histogram for this patient.

Sometimes, even with involved field RT planning and optimal technology, the gross tumor volume is so large that the safety of full-dose CCRT is questionable. In these scenarios, there are three options: (1) abort the plan for CCRT and treat the patient as if they have stage IV NSCLC (systemic therapy alone); (2) proceed with CCRT but reduce the prescribed dose of RT to a dose felt to be acceptable with respect to lung/heart tolerance metrics; (3) delay RT in favor of induction systemic therapy in the hopes that tumor shrinkage will then allow smaller and safer RT fields in several months. Each strategy has its pros and cons, and each case of this type should undergo thorough consultation with other team members in an effort to achieve a consensus.

Overall, there has been a steady improvement in the prognosis for stage III/inoperable NSCLC over four decades, as shown in Table 115-3. This results both from improvements in staging/diagnosis (i.e., stage migration) as well as better treatment. There is still much room for improvement, and patients with this category of lung cancer should be strongly encouraged to join therapeutic clinical trials.

	No. of events/ total no. of patients (%)	Median OS (95% CI), months	12-month OS rate (95% CI) %	24-month OS rate (95% CI) %	36-month OS rate (95% CI) %	48-month OS rate (95% CI) %

Figure 115-1 These figures show the 4-year overall survival (**A**) and progression-free survival (**B**) in the PACIFIC trial comparing the immune checkpoint inhibitor durvalumab versus placebo following standard chemoradiotherapy for inoperable stage III NSCLC. *(Reproduced with permission from Faivre-Finn C, Vicente D, Kurata T, et al. Four-Year Survival With Durvalumab After Chemoradiotherapy in Stage III NSCLC-an Update From the PACIFIC Trial. J Thorac Oncol. 2021;16(5):860–867.)*

DEFINITIVE RT FOR EARLY-STAGE, INOPERABLE NSCLC

Surgical resection for early-stage NSCLC remains the gold standard of care for patients with stage I disease. However, many patients with early-stage NSCLC are elderly and have significant lung disease, heart disease, and/or other relative or absolute contraindications to thoracic surgery. It has long been understood that some of these “medically inoperable” patients can be cured with RT alone. Their prognosis with respect to the lung cancer is significantly better than that for patients with stage III/technically inoperable NSCLC, and this argues in favor of early diagnosis and intervention with RT.

Historically, RT for medically inoperable early-stage NSCLC was given with large fields and a dose of 60 to 70 Gy over 6 to 7 weeks (standard fractionation), with fair results.[10] However, advances in RT hardware and planning software allow these relatively small tumor volumes to be treated with a technique called stereotactic body radiotherapy (SBRT). SBRT is analogous to gamma knife or other forms of intracranial stereotactic radiosurgery. A great many narrowly collimated radiation beams from multiple geometric angles converge on the tumor. The small tumor volume allows for a very precise and high dose of radiation to be delivered, with much lower RT doses outside of the tumor volume to the lung, heart, and other organs. SBRT dose/fractionation is usually 50 to 60 Gy given in three to eight treatments (i.e., daily dose of radiation between 7.5 and 20 Gy per fraction).

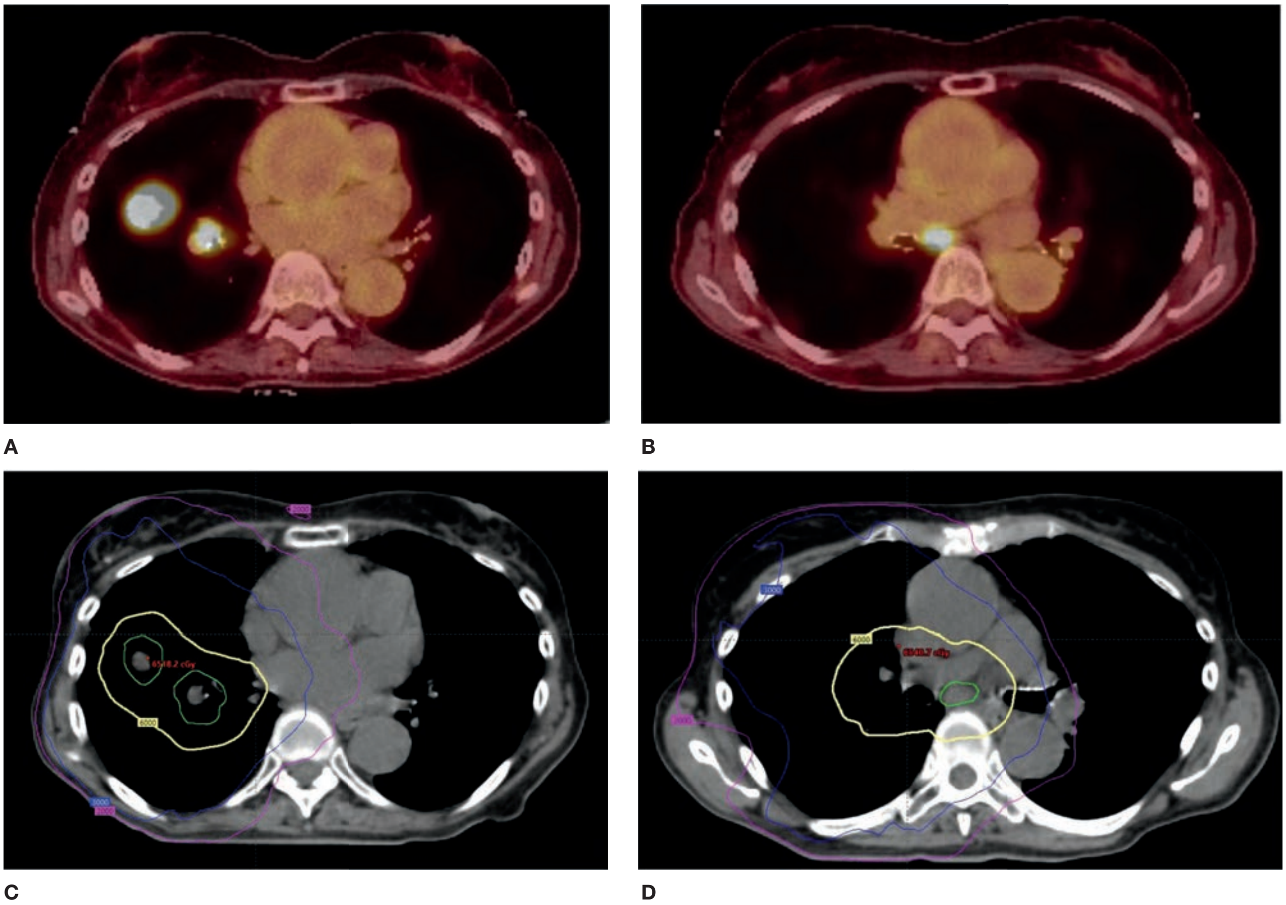

Figure 115-2 A 77-year-old female with an extensive smoking history was found to have a 2.6-cm spiculated mass in the right upper lobe on CT scan when she presented to the hospital with bronchitis. PET/CT scan showed an intensely avid primary tumor in the RUL with avid hilar adenopathy (**A**) as well as subcarinal adenopathy (**B**). She proceeded with EBUS and biopsy of the subcarinal lymph node confirming adenocarcinoma (cT1cN2; stage IIIA). She was treated with concurrent chemoradiation with carboplatin/paclitaxel. Radiation prescription was 60 Gy in 30 fractions *(yellow isodose line)* encompassing the target volume *(green contour)* with appropriate margin for microscopic disease extension and patient setup variability (**C** and **D**). The 30-Gy *(blue)* and 20-Gy *(pink)* isodose lines also are shown. The "hot spot" for the radiation plan at this axial slice is shown in *red*.

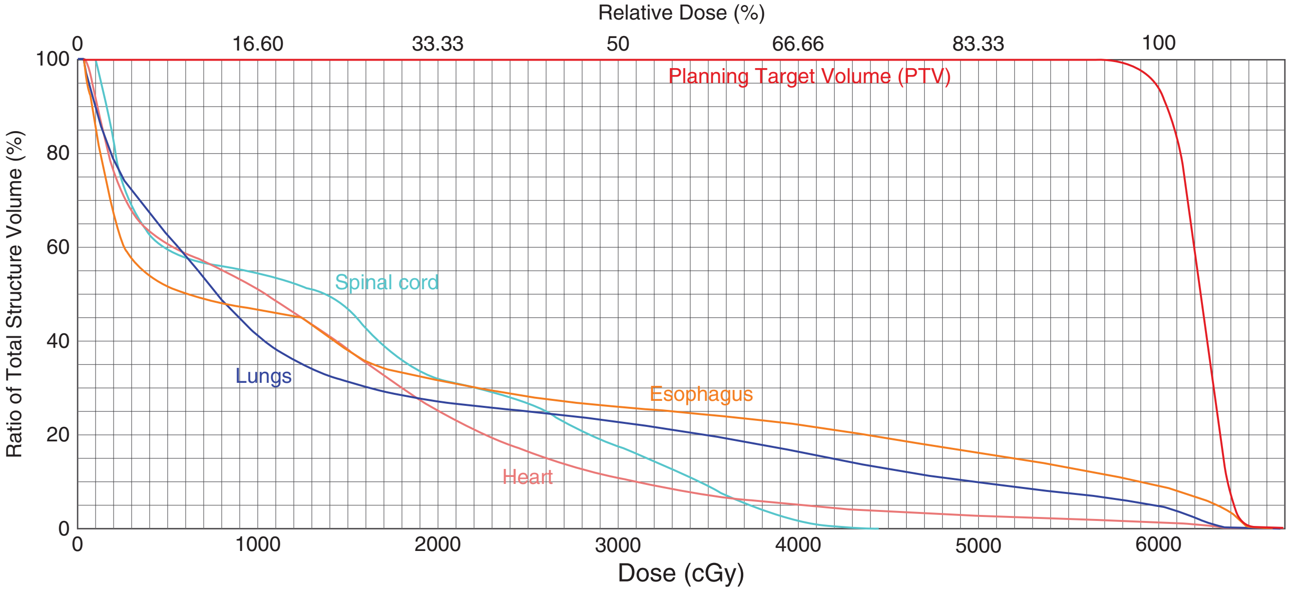

Figure 115-3 Radiation therapy dose–volume histogram (DVH) of the patient described in Fig. 115-1. On a single graph, radiation dose *(x-axis)* is plotted against the total volume of the target volume and several normal organs *(y-axis)*. As shown in this DVH, 95% of the planning target volume is receiving the prescribed dose of 60 Gy. The normal organ dose constraints that are achieved in this DVH include spinal cord maximum dose of 50 Gy, lung V20 <35%, esophagus V60 ≤15%, and heart V30 ≤25%.

TABLE 115-3 Improvement in Survival in Clinical Trials for Stage III Inoperable Lung Cancer

Treatment	Approximate Median Survival	Approximate 3-Year Survival
RT alone: 40- to 60-Gy standard fractionation/techniques[43]	10 months	10%
RT alone: 70+ Gy (or biologically equivalent accelerated techniques)[46]	12 months	15%
Sequential chemotherapy followed by RT[3]	14 months	25%
Concurrent chemoradiotherapy (technology circa 2000)[44]	17 months	35%
Concurrent chemoradiotherapy (technology circa 2010[a])[5]	29 months	50%
Concurrent chemoradiotherapy followed by immunotherapy[b,2]	47 months	65%

[a] *Modern technology includes FDG-PET–based staging and RT treatment planning, as well as higher-precision and safer RT techniques including IMRT.*

[b] *The trial documenting these results did not include patients who suffered progression and/or severe toxicity during their course of chemoradiation.*

Radiobiologically, only extremely radioresistant cells can survive this dose intensity of radiation; for typical epithelial malignancies SBRT doses are considered "ablative." A typical case of medically inoperable stage I NSCLC treated with SBRT is shown in Fig. 115-4.

Pilot studies showed not only safety, but local tumor control rates for stage I NSCLC of 85% to 95%, comparable to surgery.[11] Randomized trials showed its superiority over older standard therapy.[12,13] SBRT is now rightfully considered standard of care for inoperable stage I NSCLC. There are increasing data to suggest that

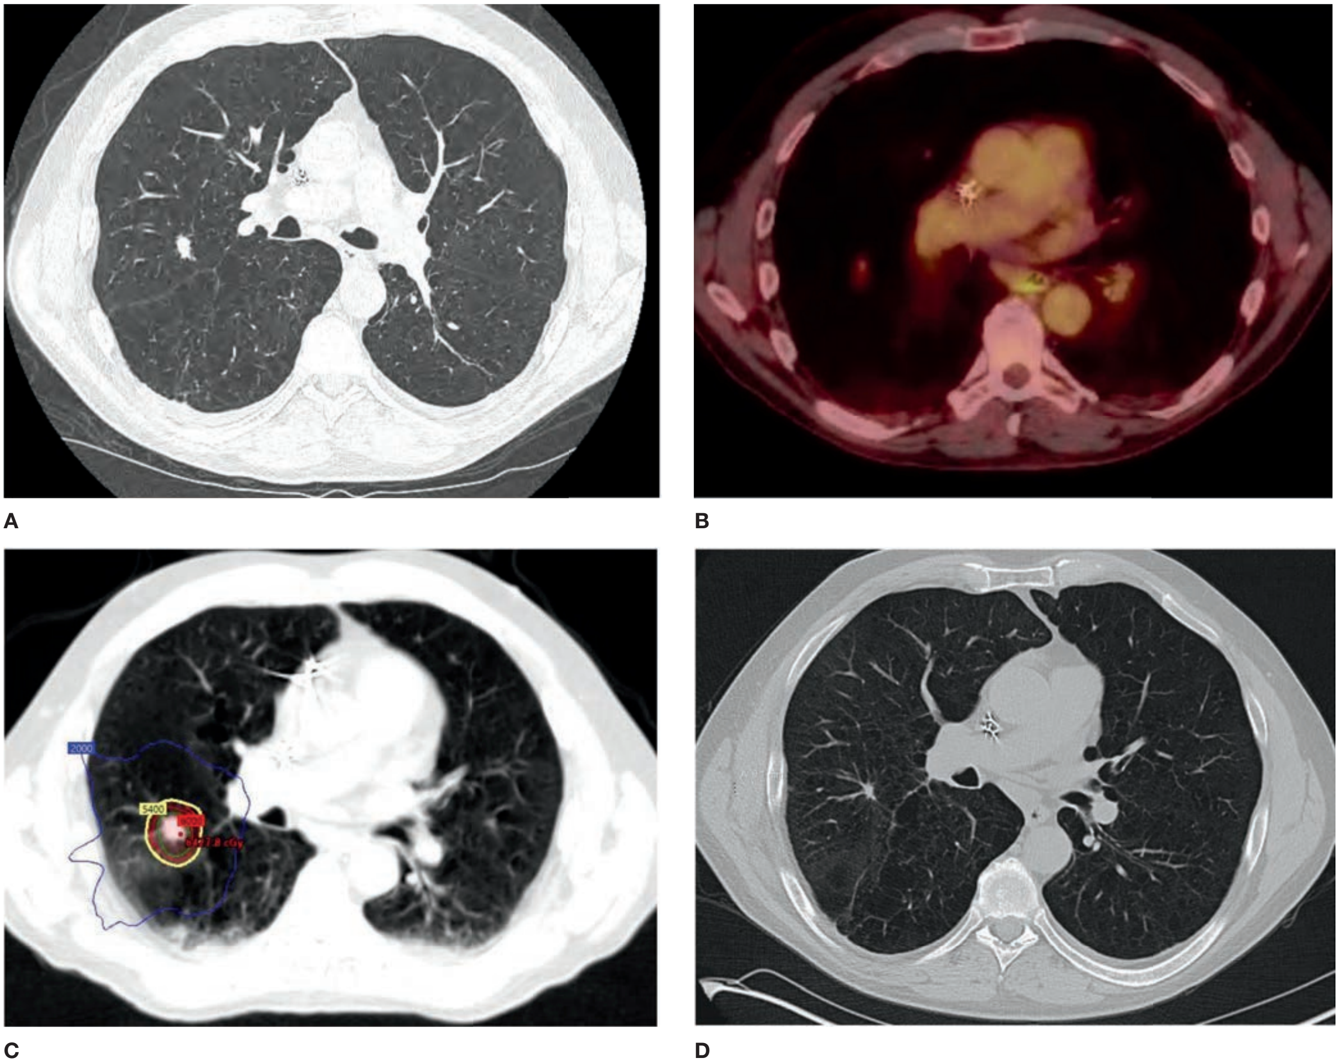

Figure 115-4 A 61-year-old man with an extensive smoking history and COPD was found to have a 1.2-cm spiculated mass in the right upper lobe on CT screening for lung cancer (**A**). A PET scan showed FDG uptake (**B**), and subsequent biopsy of the mass showed adenocarcinoma (cT1bN0, stage IA2). The patient was evaluated by a cardiothoracic surgeon, and it was determined that he was not an appropriate surgical candidate. He was treated with stereotactic body radiation therapy (SBRT) to 54 Gy in 3 fractions. The treatment plan (**C**) shows the target volume *(green)* well covered by the 54-Gy prescription isodose line *(yellow)* with further dose escalation to the target *(60-Gy isodose line in red)*. The 20-Gy isodose line *(blue)* is shown as well. CT scan 4 months after SBRT (**D**) shows a decrease in size of the treated tumor.

(1) SBRT offers results similar to surgery for patients with borderline operable NSCLC or patients with patently operable NSCLC who decline surgery;[14] (2) SBRT can be safely used for patients whose imaging data is highly consistent with stage I NSCLC but for whom biopsy was nondiagnostic and/or considered unsafe;[15] and (3) selected patients may be candidates for single-fraction SBRT (i.e., "radiosurgery") with 30 to 34 Gy.[16] Extra caution is advised when treating central tumors adjacent to the mainstem or lobar bronchi and/or great vessels.[17] At present, there is no proven role for neoadjuvant or adjuvant systemic therapy (immunotherapy or otherwise) to reduce the risk of regional or distant recurrence, although studies are underway.

PALLIATIVE RT FOR LOCAL AND/OR METASTATIC SYMPTOMATIC NSCLC

Palliative-intent RT can be extremely valuable in situations where the patient's quality of life is or may soon be substantially compromised by a localizable malignant tumor, whether in the chest or elsewhere. It has often been said that the best time to start palliative RT is "one day before the patient develops serious symptoms." Obviously, it is not possible to identify this day for any given person. Thus, the radiation oncologist—and the entire multidisciplinary team together—must use their enlightened judgment on when to intervene with RT. With more severe situations—for example, whole lung atelectasis or excruciating bone pain—the benefits of RT are low. Conversely but similarly, patients are unlikely to greatly benefit from RT to a completely asymptomatic mass that is unlikely to cause acute harm between regular follow-up/imaging intervals. Table 115-4 summarizes approximate response rates to radiotherapy for intrathoracic symptoms, recognizing that for any individual patient the likelihood of benefit is unpredictable. Unfortunately, there are no biomarkers of individual tumor radiosensitivity to predict the likelihood of benefit. The intrathoracic situations most likely to benefit from RT include low to moderate degrees of hemoptysis, pain, superior vena cava syndrome, and obstruction of central bronchi and/or pulmonary vessels. The efficacy of palliative RT in NSCLC, using moderate doses and schedules, can be profound, particularly when compared with cytotoxic chemotherapy. A variety of RT doses and schedules can be used, with no clearly shown benefit of any one schedule, at least with respect to survival.[18] A commonly used regimen in the United States is 30 Gy in 10 fractions (3 Gy per day), although shorter or slightly longer schedules are also used. These schedules commonly have temporary acute toxicities (e.g., esophagitis, fatigue) but are unlikely to cause high-grade or long-term injury to critical organs, and it is often possible to offer a repeat course when needed later in the patient's life.

For metastatic sites (e.g., painful bone, adrenal, soft tissue metastases), palliative RT can be given using similar dose/fractionation as for thoracic palliative RT. In some cases of uncomplicated bone metastases, a single 8-Gy fraction can be effective, although this may be associated with an increased likelihood of recurrence and the need for additional RT.[19] Complex bone metastases with larger volume, soft tissue extension, and/or neuropathic pain component are more commonly treated with 20 to 30 Gy over 2 to 3 weeks. SBRT, with its high-precision delivery and higher biologic dose, appears to have value for certain lesions and may improve the chance for complete pain relief and tumor control.[20]

Brain metastases from NSCLC are a special and increasingly common situation, for which a detailed discussion is beyond the scope of this chapter. Historically, the diagnosis of brain metastases would prompt an immediate course of whole-brain RT, often followed by hospice referral given the low response rate of systemic therapies. However, there have been dramatic changes in the treatment of brain metastases, including a significant increase in the number and diversity of systemic agents that cross the blood–brain barrier and have some efficacy in the brain. Whole-brain RT (WBRT) has largely been replaced by focal stereotactic radiosurgery (gamma knife and other platforms), as radiosurgery causes significantly less radiation-induced cognitive dysfunction, while simultaneously being capable of delivering ablative doses of RT to metastatic foci similar to surgery.[21,22] Although the data in favor of radiosurgery are strongest for treating one to three brain metastases, there is now substantial evidence supporting its use in much larger numbers, as long as the overall volume of metastatic disease remains modest.[23] In cases where WBRT is indicated, an IMRT technique that spares the hippocampus from high-dose RT appears to improve cognitive outcomes.[24]

TABLE 115-4 Approximate Response Rate to Radiotherapy for Common Thoracic Symptoms from Lung Cancer

Symptom	Approximate Response Rate (%)
Vocal cord paralysis	5%
Atelectasis	20%
Weight loss/anorexia	30%
Dyspnea	40%
Cough	50%
SVC syndrome	60%
Pain	70%
Hemoptysis	80%
Overall symptomatic response	**60%–75%**

NEOADJUVANT/ADJUVANT THORACIC RT

The indications for thoracic RT prior to or following definitive surgery for NSCLC are decreasing. Historically, RT was used for many cases of node-positive, resected, stage II or III NSCLC based upon the strong efficacy of RT to improve local control. However, prospective randomized trials have not demonstrated improved survival; thus, the increased local control must be weighed against the risks of RT, particularly short- and long-term cardiopulmonary risks. A detrimental effect of postoperative RT for resected, margin-negative, stage I and II (pathologic N1) NSCLC is well documented.[25] The situation in stage IIIA/N2+ NSCLC is less clear and remains controversial.[26,27] Two recent studies randomized patients with mediastinal node–positive (N2) cancer who underwent surgery and adjuvant chemotherapy to postoperative RT or no RT. There was no demonstrable benefit to postoperative RT with respect to survival, although mediastinal relapse was reduced by nearly 50%.[28,29]

Similarly, a randomized study from Switzerland showed that the addition of RT to neoadjuvant chemotherapy for "resectable" IIIA/N2 NSCLC did not improve survival despite showing trends toward improved R0 (no cancer cells seen microscopically at the primary tumor site) resection, downstaging, and pathologic complete response.[30] This study can be critiqued for being underpowered; moreover, chemoradiation was not concurrent, and the study did not employ optimal (i.e., IMRT) RT techniques. Arguably, a more important question than whether RT should be added to preoperative chemo for IIIA NSCLC is whether these patients should instead undergo nonsurgical therapy with definitive CCRT plus durvalumab. Given the prolonged accrual period needed to complete trials that address whether there is benefit to inclusion of surgery versus a nonsurgical approach, a randomized trial to address this question would be difficult to perform, as demonstrated in the 1990s/early 2000s.[31]

There are several special circumstances for adding RT to definitive surgery. The first is the important use of RT (and chemotherapy) for positive margins/residual cancer after surgery.[32,33] The sequencing of chemotherapy vis-à-vis RT in this setting remains unclear.[34] The second important indication for chemo/RT plus surgery is for superior sulcus (Pancoast) NSCLC. Failure to achieve local control for this type of lung cancer causes a devastating and often uncontrollable pain syndrome due to tumor invasion of adjacent structures such as the brachial plexus. Thus, trimodality therapy (neoadjuvant chemoradiation followed by surgery) to maximize local control is suggested.[35,36]

CONSOLIDATION (QUASI-DEFINITIVE/PALLIATIVE) RT FOR OLIGOMETASTATIC NSCLC

As noted in an earlier section, SBRT is a major advance for the treatment of stage I medically inoperable NSCLC. It is a relatively nontoxic, highly effective, and convenient treatment for small-volume lesions in the lung. These features of SBRT, and the many improvements in systemic therapy for NSCLC, have led radiation oncology investigators to expand the use of SBRT to treatment of stage IV NSCLC. The working hypothesis is that systemic therapies (whether cytotoxic, biologic-targeted, or immunotherapeutic) are most effective against microscopic subclinical metastases, while grossly evident lesions are highly likely to harbor resistant foci of cancer and/or harbor a microenvironment hostile to these systemic therapies. It has been known for decades that some patients with a single brain metastasis from NSCLC can be cured with neurosurgical resection plus brain RT, analogous to resection or radiofrequency ablation for limited liver metastases from colorectal cancer.

This line of reasoning has promoted the use of local RT for "oligometastatic" (usually defined as 1–5 metastatic foci) cancer. Several clinical trials have demonstrated the value of RT not only in controlling the irradiated lesion(s), but with regard to metrics like progression-free survival and overall survival. For example, the SABR-COMET trial, which included patients with oligometastatic disease from a number of primary sites including lung, demonstrated a 5-year survival rate of 42% among patients receiving SBRT plus systemic therapy versus 18% among patients receiving systemic therapy alone.[37] A limitation is that these trials are small and include not just lung cancer but breast, colorectal, and other cancers; SABR-COMET had 99 patients (18 with lung cancer). The NCI-supported NRG Oncology cooperative group is conducting the largest randomized study on this topic, which is extremely difficult to operationalize due to rapid changes in backbone systemic therapies (clinicaltrials.gov/ct2/show/NCT03137771).

RADIATION-RELATED TOXICITY

Toxicity from radiotherapy occurs both as acute side effects, generally defined as occurring during or within 90 days from a course of irradiation, and late effects, which become manifest 3 months or later (up to decades) after RT. Although acute and late effects of RT tend to have similar risk factors, acute effects themselves do not necessarily lead to late complications. Conversely, some patients who had minimal acute toxicities may develop significant late toxicity.

As with systemic therapy, radiation toxicity is graded on a 1 to 5 scale, with grade 1 representing mild effects (e.g., mild dyspnea on exertion) and grade 5 representing fatal toxicity. Radiation toxicities differ from systemic therapy in that the effects almost universally occur only in the irradiated tissue volumes. Some effects of radiation are more generalized, including fatigue and immunosuppression. In the treatment of thoracic malignancies, where high radiation doses and large fields are often needed, the organs of greatest concern for both acute and late complications are the lung, heart, and esophagus. Significant dermatologic toxicity is rare with modern megavoltage equipment, and likewise with modern treatment planning technology the risk to the thoracic spinal cord is low. Other structures prone to injury from high-dose radiation include the brachial plexus, the tracheobronchial tree, the great vessels, and bones; concern about these organs has become of greater interest in the era of high-dose SBRT. Although many complications of RT are manageable, the most important strategy is prevention through sophisticated treatment planning and appropriate patient selection.

■ Lung Complications

Radiation-induced lung injury (pneumonitis and fibrosis) is the most common serious complication of thoracic irradiation. It usually appears between 1 and 4 months after irradiation, but it may occur during a course of particularly intensive (chemo)radiotherapy. Dyspnea is the hallmark symptom, along with cough, low-grade fever, malaise, and sometimes pleuritic chest pain. See Figure 115-5 for a classic case example of radiation pneumopathy after aggressive, curative-intent thoracic chemoradiotherapy. Most cases are more subtle and require computed tomography imaging to assist in the differential diagnosis and followup.

The differential diagnosis is broad, and radiation pneumonitis should not automatically be assumed solely because of temporal relationship. A key feature of radiation pneumonitis is its general confinement to the irradiated lung volume, and comparison between CT opacities and the radiation port is an essential step in making the diagnosis. In addition to chest CT imaging, bronchoscopy may be indicated to rule out infection or tumor recurrence/progression.

Radiation pneumonitis is often but not invariably steroid responsive. For more severe cases, a high dose (60 mg prednisone per day or equivalent) for 1 to 2 weeks is initiated followed by a slow taper over 3 to 12 weeks.[38] In contrast, the long-term phase of radiation-induced lung injury, radiation fibrosis, has no known effective treatment.

Given the limited treatment options for radiation-induced lung injury, the main strategy is minimization of the risk. The most significant risk factor for high-grade radiation pneumonitis is the volume of lung irradiated. Other factors associated with a higher risk include radiation dose and dose per fraction (larger dose per fraction increases risk) and tumor location (lower lobe lesions appear to have a higher risk). Poor pulmonary function before treatment also increases the risks of serious lung injury; in particular, pre-RT idiopathic pulmonary fibrosis predisposes to high-grade radiation pneumonitis and is a relative contraindication to thoracic RT.[39] Connective tissue diseases like systemic lupus erythematosus or scleroderma also raise concerns.[40] Certain chemotherapy agents, especially anthracyclines, methotrexate, bleomycin, and mitomycin, have long been recognized as exacerbating radiation lung injury, and these drugs are rarely used with thoracic RT today. Concurrent administration of carboplatin/paclitaxel has been associated with increased risk compared with cisplatin/etoposide.[41] The data are still evolving on the use of immunotherapy concurrent with radiation.

In radiation treatment planning, particular attention is given to the "V20"—the percent volume of the patient's total lung volume irradiated to 20 Gy or more.[41] Radiation planning should prioritize achieving V20 levels less than 30%. As the V20 rises above 37%, the risk of grade 3 pneumonitis exceeds 15%, and the risk of grade 4 to 5 (acute respiratory distress syndrome and/or death) increases significantly.

Modern radiation techniques like IMRT or proton beam therapy offer better lung V20s and appear safer than classic conformal RT fields.[42] With SBRT for a small stage I NSCLC, lung toxicity is remarkably mild, particularly if the irradiated lung field is peripheral and already mostly nonfunctional. There is no measurable biomarker to predict radiation-induced lung injury; research has focused on measuring cytokine profiles (e.g., TNF-α, TGF-β, IL-6), but these hypotheses have not yet been validated.

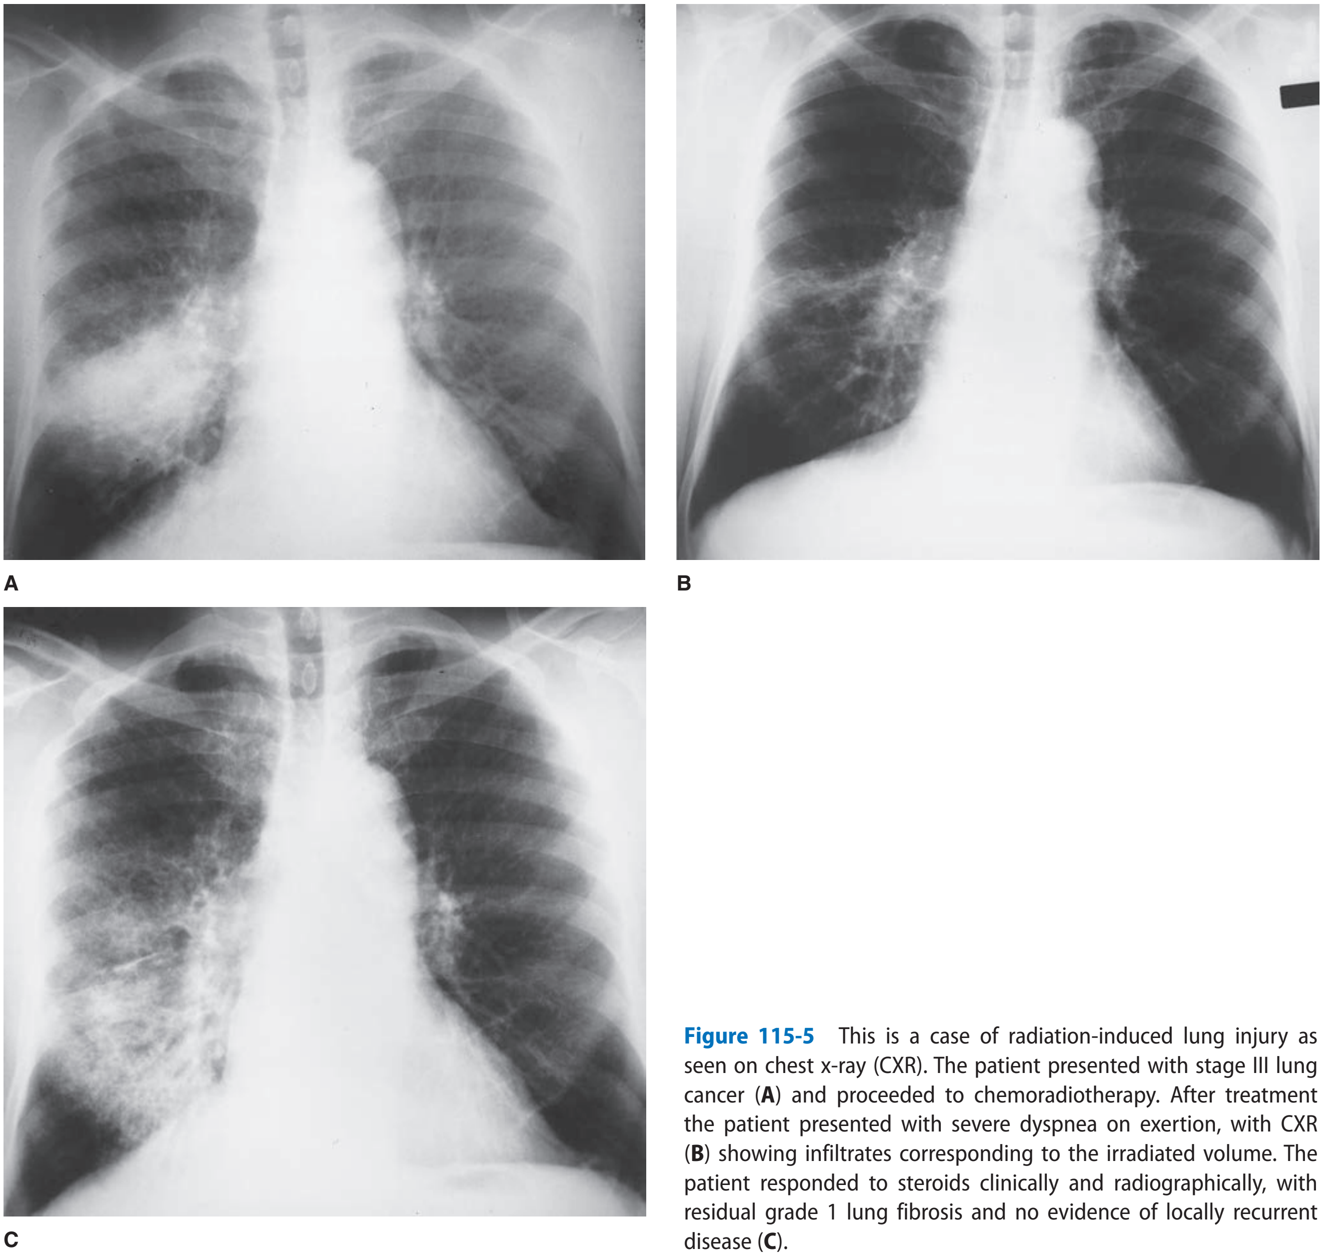

Figure 115-5 This is a case of radiation-induced lung injury as seen on chest x-ray (CXR). The patient presented with stage III lung cancer (**A**) and proceeded to chemoradiotherapy. After treatment the patient presented with severe dyspnea on exertion, with CXR (**B**) showing infiltrates corresponding to the irradiated volume. The patient responded to steroids clinically and radiographically, with residual grade 1 lung fibrosis and no evidence of locally recurrent disease (**C**).

■ Cardiac Toxicity

In addition to lung toxicity, there is increased recognition of the importance of cardiac toxicity from radiation in lung cancer patients[43] This is not unexpected based upon longstanding experience in breast cancer and lymphoma patients and is likely to become an increasing challenge as lung cancer patients are living longer. Indeed, cardiac injury is hypothesized as a reason ultra-high-dose (74 Gy) radiotherapy for stage III cancer or postoperative radiotherapy for resected stage II cancer may be more detrimental than beneficial.[5,25]

Cardiac events occurring during a course of RT are more likely to be related to the tumor itself (e.g., atrial fibrillation due to tumor invasion of the pericardium) and/or underlying cardiac disease. Acute cardiac complications (during or within several months post-RT) such as radiation pericarditis and associated dysrhythmias occur in about 5% of patients. Most cases are self-limited and treated with appropriate medications. Pericardiocentesis or other invasive procedures are rarely required.

As with lung toxicity, the risk of cardiac complications from RT is highly dependent upon the radiation dose and volume of heart irradiated. Longer-term cardiac complications include accelerated atherosclerosis, valvular disease, and cardiomyopathy. There is no clear threshold radiation dose/volume relationship to cardiac toxicity, although metrics of interest include V30 (percent of total cardiac volume irradiated to 30 Gy or more) and mean heart dose. This is somewhat analogous to radiation planning to minimize lung injury. However, it has added complexity because certain substructures of the heart (e.g., left anterior descending coronary artery) are more critical than others. Proton irradiation appears to be associated with improved radiation dosimetry for the heart, but this has not yet been shown to translate into better outcomes.[42]

■ Esophageal Toxicity

Esophageal toxicity from RT is primarily an acute problem. It is a nearly universal side effect of RT when treating mediastinal nodes and is significantly worse with chemoradiation than RT alone.[44] However, it is usually self-limited, and the risk of long-term complications like stricture approximates 10% with the standard RT dose of 60 Gy. Acute radiation esophagitis usually responds well to topical anesthetics and oral pain medications, and strictures can be managed with endoscopic dilatation. With ultra-high-dose radiotherapy to the mediastinum (70+ Gy), or with overlapping reirradiation, there is a risk of tracheoesophageal fistula, particularly in the presence of active tumor in this region.

Other End-organ Toxicities

No organ is completely resistant to radiation injury. One of the most feared complications from radiation therapy is spinal cord myelopathy. Fortunately this is rare today (<1% risk), with modern technology to reliably limit cumulative spinal cord dose to less than 50 Gy. Similarly, brachial plexopathy is uncommon with RT doses of 60 Gy or less, although patients irradiated for superior sulcus tumors are particularly susceptible.

A more recent phenomenon is the occurrence of chronic localized chest wall pain and/or rib fracture following SBRT for peripheral lung cancers.[45] This may occur years following radiation and can mimic pathologic fracture from tumor recurrence/metastasis.

With the use of higher-dose RT, including SBRT, patients are at risk for serious complications to critical structures in the mediastinum and hilum, including the tracheobronchial tree and great vessels. Patients treated with high-dose SBRT for central stage I cancers (within 2 cm of a lobar bronchus) are at risk for massive fatal pulmonary hemorrhage. Although this is uncommon (<5%), this has led to caution with the use of SBRT for such patients.

SUMMARY

RT plays a major role in the treatment of NSCLC. It is the primary treatment (with systemic therapy) for inoperable, nonmetastatic NSCLC and there have been considerable improvements in local control and other outcomes in recent decades. Of particular note, patients with medically inoperable early-stage NSCLC have a good chance for durable disease control with appropriately planned and delivered SBRT. In addition to its value as definitive therapy, RT benefits selected patients when given as adjuvant or neoadjuvant therapy. There are also a number of patients with oligometastatic stage IV NSCLC for whom RT may improve survival when added to systemic therapy. Finally, RT is of critical importance as part of palliative treatment for advanced incurable disease, both in the chest and at distant metastatic sites.

CHAPTER 116

Small Cell Lung Cancer: Diagnosis, Treatment, and Natural History

Jonathan E. Dowell
Benjamin J. Drapkin
David E. Gerber
David H. Johnson

INTRODUCTION

Small-cell lung cancer (SCLC) is, in many ways, a unique tumor. Untreated, it is a highly virulent malignancy, with a life expectancy best measured in weeks. Conversely, it displays exquisite chemosensitivity, resulting in partial or complete responses in the majority of cases. For the first time in more than 30 years, the standard of care for advanced SCLC has changed with the addition of immune checkpoint inhibitor therapy to standard chemotherapy. Unfortunately, even with this advance, durable tumor responses are rare, and as a result, more than 95% of SCLC patients die from their disease. This chapter reviews the biology, epidemiology, diagnosis, clinical presentation, staging, and current management of this difficult disease.

EPIDEMIOLOGY

Lung cancer remains the leading cause of cancer death in men and women in the United States. In 2021, estimates call for 235,760 cases of newly diagnosed lung cancer (119,100 men and 116,660 women) and 131,880 deaths (69,410 in men and 62,470 in women).[1] Smoking tobacco products is the leading cause of lung cancer, conferring a 20-fold increase in risk and accounting for approximately 90% of all cases,[2] and smoking cessation reduces this risk substantially.[3] The prevalence of smoking in the United States peaked in 1964 at 42.7% with the landmark surgeon general's report on Smoking and Health. Since that report, the percentage of ever-smokers who have successfully quit smoking, or "quit ratio," has steadily increased to 61.7% in 2017, meaning that are currently more former smokers than current smokers, and the prevalence of smoking has declined below 18%.[4] The incidence of lung cancer lagged behind smoking cessation by just under three decades, but it has steadily declined by nearly 30% from its peak in 1982.[5] One study predicts that continued decline in smoking prevalence will reduce lung cancer deaths to 50,000 annually by 2065, a 60% reduction, despite increasing population and life expectancy.[6]

SCLC is more tightly associated with smoking than any other histologic subtype of lung cancer, with only 2% of cases occurring in never-smokers[7–9] and a relative risk that increases sharply with duration and intensity of exposure.[10] COPD is an independent risk factor for SCLC and mediates a small proportion of the smoking risk effect.[11] Other proposed risk factors include exposure to bis(chloromethyl) ether, nickel, vinyl chloride, asbestos, cadmium, radon, arsenic, and radiation, but the impact of each of these agents is not well quantified.[12] Due to the tight association between SCLC and tobacco use, smoking cessation had a greater impact on SCLC than other types of lung cancer, decreasing proportional incidence from a peak of 17% of all lung cancer in 1986 to 13% in 2002, where it has remained as of 2017.[5,13] SCLC mortality has declined in parallel with incidence and can be attributed almost entirely to smoking cessation, as survival following diagnosis has remained brief. In contrast, non–small-cell lung cancer (NSCLC) mortality decreased twice as rapidly as incidence (6.3% vs. 3.1% annually), reflecting a marked improvement in survival following diagnosis attributable to advances in therapies.[14]

PATHOLOGY

In 1926 William George Barnard published the first report of SCLC, in which he described mediastinal tumors of epithelial origin that he called "oat cell sarcoma" due to the histologic resemblance of the cells to oat grains.[15] Following this initial description, a series of classification systems were developed to divide SCLC into a variety of subtypes, but these were of limited clinical utility. In 1999 the WHO revised the classification of neuroendocrine lung tumors into four diagnoses by histologic grade: low-grade typical carcinoid (TC), intermediate-grade atypical carcinoid (AC), and two high-grade tumors, SCLC and large cell neuroendocrine carcinoma (LCNEC) (Table 116-1).[16]

This system has remained largely intact in the most recent WHO classification of lung tumors, published in 2015, in which only two subtypes of SCLC are recognized: pure SCLC and combined SCLC, in which another NSCLC component is present.[17] If the combined NSCLC component is LCNEC then it must be present in at least 10% of the tumor due to histologic similarity, but for

TABLE 116-1 Features of Neuroendocrine Lung Tumors

	Typical Carcinoid	Atypical Carcinoid	LCNEC	SCLC
NE features	Well differentiated	Well differentiated	Poorly differentiated	Poorly differentiated
Cell size	Intermediate	Intermediate	Large to intermediate	Small to intermediate
Mitotic rate	Low <2 mitoses/2 mm^2	Intermediate 2–10 mitoses/2 mm^2	High median 70 mitoses/2 mm^2	High median 80 mitoses/2 mm^2
NE markers by IHC	+++	++-+++	+-+++	±
Necrosis	—	+ (focal)	+++	+++
Ki-67 index	≤5%	5–20%	50–100%	80–100%
5-year survival	90–95%	60–70%	10–40%	≤5–10%

IHC, immunohistochemistry; LCNEC, large cell neuroendocrine carcinoma; NE, neuroendocrine; SCLC, small cell lung cancer.

mixed adenocarcinoma or squamous cell carcinoma there is no fractional requirement.[18] Approximately 20% of SCLC is combined with NSCLC, most frequently LCNEC, but this estimate is based on surgical and autopsy series,[19,20] whereas the majority of diagnostic SCLC samples are small biopsies in which combined histology is difficult to recognize.

SCLC usually arises as a perihilar tumor, but in 95% of cases it presents as disseminated disease with mediastinal lymph node metastases that are often more prominent than the primary tumor.[21] Because there is no curative role for surgical resection in these cases, the vast majority of SCLC pathology samples are small biopsies or cytologic specimens from sites of metastasis. In the 2015 WHO classification of lung tumors, a specific approach to diagnosis using cytologic specimens was proposed, and although biopsy specimens are ideal, cytology alone is 60% to 90% sensitive and more than 95% specific for SCLC.[22,23]

The hallmark features of SCLC can be discerned by light microscopy, and although immunohistochemistry may be helpful for the diagnosis in some cases, the most important stains are hematoxylin and eosin (H&E). On H&E slides at low power, SCLC appears blue owing to the high nuclear-to-cytoplasmic (N:C) ratio, relatively basophilic cytoplasm, and scant extracellular matrix, which immediately distinguishes it from the more eosinophilic NSCLCs.[24] At higher magnification, tumor cells are small (<3 lymphocyte diameters, or ~ 20 μm) and round or spindle-shaped; they have scant cytoplasm, poorly defined borders, granular evenly distributed chromatin ("salt and pepper") and absent or inconspicuous nucleoli.[25] Nuclei are often deformed by adjacent tumor cells and structures, termed "nuclear molding" **(Fig. 116-1)**.

The predominant architecture of SCLC is dense sheets of cells with extensive areas of crush artifact and necrosis, and samples lack the glandular architectures of adenocarcinoma or keratinization of squamous cell carcinoma. Architecture is not entirely absent, as isolated areas may organize into rosettes (nuclei surrounding an eosinophilic cell-free center), trabeculae (ribbons of adjacent interlocking cells slightly overriding one another), palisades (parallel rows of cells), or nests (clumps of cells surrounded by stroma).[26]

Both apoptotic and mitotic figures are frequent, with an average of 60 mitoses per 2 mm^2 (8–10 high-powered fields).[24] Mitotic counts distinguish SCLC and LCNEC from the lower-grade pulmonary carcinoid tumors, with a threshold of at least 11 per 2 mm^2 required for diagnosis.

Although immunohistochemistry is not required for diagnosis of SCLC, it reduces interobserver variability by confirming expression of neuroendocrine markers and ruling out non-neuroendocrine lineages.[27] Immunohistochemistry is particularly useful in small biopsies and cytology specimens with crush artifact to distinguish SCLC from crushed carcinoid or lymphoma, as Ki-67 staining should be high (80%–100%) and lymphoid markers negative.[25,28] The classic neuroendocrine markers include synaptophysin, chromogranin A, and neural cell adhesion molecule (NCAM, CD56). Synaptophysin and chromogranin A are components of neurosecretory granules and synaptic vesicles, respectively, and are specific markers of neuroendocrine differentiation in lung tumors. CD56 is more sensitive for SCLC—positive in more than 90% of cases—but is not as specific, as CD56 is expressed in skeletal muscle and leukocyte subsets, as well as in 5% to 15% of NSCLC excluding LCNEC and more than 70% of mesotheliomas.[29–32] A fourth neuroendocrine marker, insulinoma-associated protein 1 (INSM1), has recently entered clinical practice and may have greater sensitivity and specificity than the other three markers alone or in combination.[30,33–36] INSM1 is a transcription factor expressed in developing neuroendocrine tissue during embryogenesis, and its nuclear localization may aid in straightforward diagnosis of SCLC.[29,37] All four neuroendocrine IHC markers (synaptophysin, chromogranin A, CD56, INSM1) may be negative or low in 10% of SCLC cases that nevertheless meet morphologic criteria for diagnosis.[29] Emerging research suggests that a substantial fraction of these neuroendocrine-low SCLC cases may be driven by POU domain class 2 transcription factor 3 (POU2F3), a transcription factor that normally regulates chemosensory tuft cell development, but this tuft-cell variant has not yet impacted diagnosis or clinical management.[38,39]

Non-neuroendocrine lung tumors that may mimic the cellular morphology and tissue architecture of SCLC include basaloid squamous cell carcinoma, poorly differentiated adenocarcinoma, NUT carcinoma, melanoma, lymphoma, Ewing sarcoma, and desmoplastic small round cell tumor (DSRCT).[24] In addition to absence of neuroendocrine markers, positive immunohistochemical markers may be used to exclude these diagnoses. Pure SCLC lacks expression for p40 or Napsin A, which mark squamous cell carcinomas and adenocarcinomas, respectively.[40,41] In contrast, TTF-1 (thyroid transcription factor 1, NKX2.1) is positive in the majority (>80%) of both SCLC and adenocarcinoma and does not distinguish these entities.[42–44] SCLC tumors express low-molecular-weight cytokeratins and stain positively with broad-spectrum antibody cocktails such as AE1/AE3. Low or absent cytokeratin staining supports non-epithelial diagnoses such as lymphoma, sarcoma, or melanoma, which may be further distinguished by positive CD45 immunohistochemical staining in lymphoma,

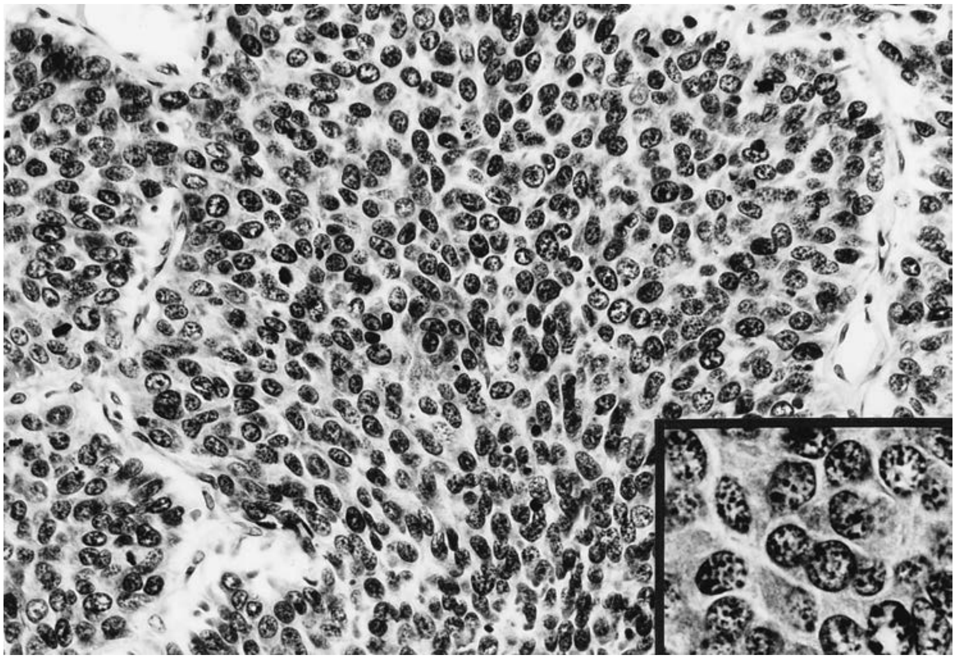

Figure 116-1 Photomicrograph of pure small-cell carcinoma, demonstrating a homogeneous cell population with salt-and-pepper chromatin and moderately prominent nucleoli (H&E, 250×; *inset* 400×). *(Reproduced with permission from Dr. Michael T. Lomis, Vanderbilt University.)*

CD99 in Ewing sarcoma or DSRCT (with desmin), or melanocytic markers such as S-100 in melanoma.[18,45,46] Strong uniform nuclear staining of NUT protein is diagnostic for NUT carcinoma, and this can be confirmed by fluorescence in-situ hybridization (FISH) detection of the *NUTM1* rearrangement.[47] Merkel cell carcinoma is a neuroendocrine skin cancer that may first present as a cancer of unknown primary with bulky mediastinal metastases, mimicking SCLC. These cases may be distinguished by expression of the high-molecular-weight cytokeratin CK20 and absence of TTF-1.[48]

TUMOR BIOLOGY

The genomic drivers of SCLC tumorigenesis have been identified though complementary efforts to discover recurrent alterations in human tumors and cell lines, and to test the tumorigenic potential of these alterations in genetically engineered mouse models (GEMMs). The first SCLC genome was reported in 2010 and sequenced from a cell line established at the National Cancer Institute Navy Medical Oncology Branch in 1979, NCI-H209.[49,50] This cell line demonstrated the three genomic hallmarks of SCLC: (1) a high tumor mutational burden with a predominant C>A transversion signature due to tobacco carcinogens, (2) biallelic loss of Retinoblastoma 1 (*RB1*), the first gene ever identified as a tumor suppressor, and (3) biallelic loss of tumor protein 53 (*TP53*), the most commonly mutated gene in human cancer.[18,51–53] In mice, pulmonary neuroendocrine cells engineered for deletion of *RB1* and *TP53* produce SCLC tumors with a 10- to 12-month latency, confirming that these alterations drive tumorigenesis.[54]

SCLC is almost never surgically resected or biopsied after diagnosis, and the scarcity of fresh-frozen specimens has restricted genomic profiling. Despite a higher incidence than glioblastoma, acute myeloid leukemia, or diffuse large B-cell lymphoma, SCLC is not represented among the 37 cancers sequenced in the Cancer Genome Atlas.[5,55] The NCI-H209 genome was followed by two small studies of primary tumors, representing 36 and 29 patients.[56,57] The largest effort to date, published in 2015, scoured global tissue repositories to obtain 110 fresh-frozen samples suitable for whole genome sequencing.[58] For these studies, tumor samples were obtained almost exclusively from untreated patients and enriched for early-stage disease. These studies confirmed the near-universal loss of *RB1* and *TP53* observed in cell lines, but these mutations cannot be targeted by current therapies and are so prevalent that they do not define SCLC subclasses that might respond to different therapies. Mutations in *RB1* and *TP53* are both tumor-defining and clinically inert.

Genomic profiles of SCLC have not revealed targetable oncogenic drivers, such as the activating mutations in *EGFR* and rearrangements in *ALK* that began the era of targeted therapy in NSCLC.[59–62] However, recurrent genomic alterations that occur in subsets of cases have been demonstrated to drive SCLC tumorigenesis or promote tumor growth in laboratory models, and may serve as future targets for new therapies. These include amplifications in MYC family genes (*MYC, MYCL1,* and *MYCN*), *BCL2, SOX2,* and *FGFR1*; inactivating mutations in the RB-related genes *RBL1* (p107) and *RBL2* (p130); mutations in histone modifying enzymes *CREBBP*, *EP300*, *MLL,* and *KMT2D;* inactivation of NOTCH family receptors *NOTCH1-4*; activating mutations in the PI3 kinase (PI3K) catalytic subunit *PIK3CA* or deletion of the opposing phosphatase *PTEN*; and dominant negative mutations in the tumor suppressor *TP73*.[56–58,63–79] None of these genomic alterations is present in more than 15% of cases, and only the MYC family amplifications and NOTCH family mutations are mutually exclusive, with the caveat that these relationships are imprecise due to the small number of samples.

Gene expression profiles of SCLC have provided more fertile ground for development of new treatment strategies. Differential expression of PARP1 (poly-ADP-ribose polymerase 1) between SCLC and NSCLC led to the discovery that SCLC cells are exquisitely sensitive to PARP inhibitors in vitro, and promising early-phase trials of PARP inhibitor combinations have been reported or are accruing as of 2021.[80–82] Similarly, the cis-acting NOTCH inhibitor DLL3 (delta-like ligand 3) is not expressed outside the central nervous system and is both sensitive and specific for SCLC. Initial attempts to target DLL3 with antibody–drug conjugates proved highly effective in laboratory models but toxic in patients and remain an active area of translational investigation.[83–85] A molecular subclassification for SCLC has been proposed based on dominant expression of one of four lineage-defining transcriptional regulators: ASCL1, NEUROD1, POU2F3, and YAP1.[86] This subclassification is currently in rough-draft form and undergoing frequent experimental revision, but when more mature it may help to focus development of new therapies on the patients most likely to benefit.[18]

NATURAL HISTORY

The natural history of untreated SCLC is characterized by early dissemination and death. Unlike NSCLC, it is always considered a systemic disease at diagnosis, even if it appears clinically confined to the chest. Postmortem examinations performed on patients who died from other causes shortly after the "complete" surgical resection of their SCLC have demonstrated identifiable metastases in up to 70% of cases.[87] Evidence of distant spread can be found in virtually any organ system. The most common sites of involvement, however, are the liver, bone and bone marrow, and central nervous system (CNS) (Table 116-2).[88] This pattern of spread dictates how the search for metastatic disease is undertaken (see "Staging and Pretreatment Evaluation," below).

Patients with SCLC have a short life expectancy if therapy is not initiated in a timely fashion. The median survival for untreated patients is 4 to 6 months if they have disease that is apparently confined to the chest (limited stage [LS]), and 5 to 9 weeks if they present with metastatic disease. With therapy, survival improves significantly (see "Treatment," below). Chemotherapy with or without irradiation can extend median survival to an average of 14 to 20 months for those with thorax-confined disease and 7 to 10 months for those with more extensive spread. Recent trials indicate that 2-year survival may be as high as 40% for aggressively treated LS patients. Two- to three-year survival remains under 5% for those with metastatic disease.

TABLE 116-2 Involvement of Extrathoracic Sites at Diagnosis After Pretreatment Staging Studies in Small Cell Lung Cancer

Extrathoracic Site	Patients with Finding (%)
Final stage	
Limited stage	30–40
Extensive stage	60–70
Bone	19–38
Liver	17–34
Bone marrow	17–23
Brain	0–14
Lymph nodes	7–25
Soft tissue	3–11

Staging evaluation and prognostic factors in small cell lung cancer In Aisner J, ed. Lung cancer. New York, NY; Churchill Livingstone; 1985:241–268.

SCREENING

Lung cancer screening with annual low-dose computed tomography (LDCT) was endorsed by the United States Preventive Services Task Force (USPSTF) in 2013 and first covered by the Centers for Medicare and Medicaid in 2015. Eligible individuals are age 50 to 80 years (USPSTF) or 55 to 77 years (Medicare), have smoked 20 pack-years, and if former smokers have quit within the prior 15 years. In the National Lung Screening Trial (NLST) and in the European NELSON trial, LDCT-based lung cancer screening reduced lung cancer and overall mortality.[89,90] Nevertheless, it remains largely underutilized, with fewer than 5% of eligible patients in the United States undergoing screening.[91]

Although heavy smokers have the greatest likelihood of developing SCLC, the benefit of lung cancer screening appears tied almost exclusively to early detection of NSCLC. In an analysis of 5134 individuals enrolled in 2 lung cancer screening trials, 10 cases of SCLC were reported, accounting for only 6% of the lung cancer cases identified.[92] Notably, these patients had median cumulative tobacco consumption of 82 pack-years, compared to 39 pack-years for the overall study population and 46 pack-years for subjects diagnosed with NSCLC. At diagnosis, stage distribution was as follows: IV (70%), III (20%), I (10%). None of the patients survived 3 years. This experience mirrors that in the NELSON trial, where SCLC accounted for only 7% of reported tumors, and only half of these cases were initially detected by LDCT.[90]

STAGING AND PRETREATMENT EVALUATION

Staging a cancer defines the anatomic extent of the tumor, helps determine prognosis, and guides treatment options. The official staging for SCLC is the same as for NSCLC and utilizes the American Joint Cancer Commission staging system, which defines stage based on the extent of the primary tumor, the degree of nodal involvement, and the presence or absence of distant metastasis (TNM staging). Virtually all clinicians, however, prefer the original staging system for SCLC proposed several decades ago by the Veterans Affairs Lung Cancer Study Group as it better segregates patients into two groups with clearly different prognoses and treatment options. In this system, disease confined to one hemithorax that is able to be encompassed by a single, tolerable radiation port is considered LS.[93] This typically includes patients with hilar, mediastinal, and ipsilateral supraclavicular lymphadenopathy. There is debate regarding whether patients with contralateral hilar and supraclavicular lymphadenopathy or those with ipsilateral pleural effusion should be placed in the LS category. However, most clinical trials for LS disease exclude these patients. Any spread of disease beyond the extent described earlier is defined as extensive-stage (ES) disease. A third stage ("very limited-stage [VLS] disease") has been proposed by some to define those patients with small primary tumors and no identifiable regional lymphadenopathy or distant metastases, as this group of patients may be considered for surgery (see "Treatment," below). In most modern series, the majority of patients (60%–65%) present with ES disease, with LS (30%–35%) and VLS (<5%) making up the remainder.[13,94]

Once a diagnosis of SCLC is established the initial pretreatment evaluation should include a complete history and physical examination, and basic laboratory studies including a complete blood count (CBC), serum electrolytes, and liver and renal function tests. A serum lactate dehydrogenase (LDH) level may provide additional prognostic information (see "Prognostic Factors," below). Current guidelines call for CT scans of the chest (including the liver and adrenal glands) as initial imaging. Some 10% to 18% of SCLC patients have brain involvement at presentation,[95,96] and it is therefore recommended by many that all patients with SCLC undergo imaging of the brain at diagnosis, preferably magnetic resonance imaging (MRI). Certainly, those patients with symptoms suggesting brain involvement require prompt evaluation.

Bone metastases from SCLC are also frequent at presentation. Historically, bone scan was the study of choice to evaluate those patients with bony symptoms or an elevated alkaline phosphatase suggesting possible spread of disease to the bone. Fluorodeoxyglucose positron emission tomography (FDG-PET) has supplanted bone scan at most centers. SCLC is a highly metabolically active tumor and is therefore typically quite FDG avid at both the primary and metastatic sites. Case series suggest that PET scan can improve staging accuracy in SCLC and that PET will correctly upstage as many as 19% of patients previously thought to have LS disease.[97–102]

Another staging procedure of historic interest is bone marrow biopsy and aspiration. SCLC is one of a few cancers known to commonly cause bone marrow metastases, and as a result, bone marrow evaluation was standard in SCLC patients for many years. However, most patients with bone marrow involvement have significant abnormalities on their CBC (notably leukoerythroblastosis), and exceedingly few patients have bone marrow as the only site of metastasis. Therefore, the utility of this test appears limited to those few patients with LS disease after complete radiographic staging who have an abnormal CBC.

In general, with the possible exception of brain imaging to rule out occult disease, once the presence of metastatic SCLC has been established, further radiographic evaluation to identify additional sites of metastatic disease is not warranted. In that setting, subsequent evaluation should be symptom guided.

CLINICAL PRESENTATION

No aspect of the clinical presentation of SCLC distinguishes it from NSCLC or even from neoplasms metastatic to the lungs. However, the duration of time from the development of symptoms to the diagnosis of SCLC tends to be very short, due to the rapid dissemination of the disease. The typical patient is a middle-aged or elderly smoker who presents with symptoms attributable to pulmonary and mediastinal disease: cough, dyspnea, chest pain, hoarseness, and/or hemoptysis. Because of the usual endobronchial location of the tumor, patients often have accompanying postobstructive pneumonia.

Constitutional symptoms may include weakness, anorexia, weight loss, and, rarely, fever. Symptoms may also arise from distant metastases, including headache or seizures in patients with CNS disease, and abdominal or bone pain with hepatic and osseous metastases. Symptoms may also reflect regional spread with attendant superior vena cava obstruction, manifesting as facial fullness, upper extremity swelling, headache, and dysphagia. In rare instances, patients present with symptoms from a paraneoplastic syndrome. The more common of these rare presentations are syndrome of inappropriate antidiuretic hormone secretion (SIADH) and other causes of hyponatremia, Cushing syndrome, Lambert–Eaton syndrome, and other paraneoplastic neuropathies or neurologic disorders (see "Paraneoplastic Phenomena," below).

Physical examination may yield only the stigmata of chronic obstructive pulmonary disease, or it may demonstrate lymphadenopathy, hepatomegaly, bone tenderness, or neurologic findings. Signs of the superior vena cava syndrome include venous distention of the neck and chest wall, cyanosis, facial plethora, and upper extremity edema.

Radiographic studies typically demonstrate a central mass (75% of patients) with or without hilar nodal involvement (Figs. 116-2–116-4). Postobstructive atelectasis and pneumonia are very common with SCLC, but cavitation is rare and suggests the alternative diagnosis of squamous cell lung cancer.

Laboratory evaluation reveals an elevated LDH in about 50% of patients. Liver function tests may be abnormal in those with

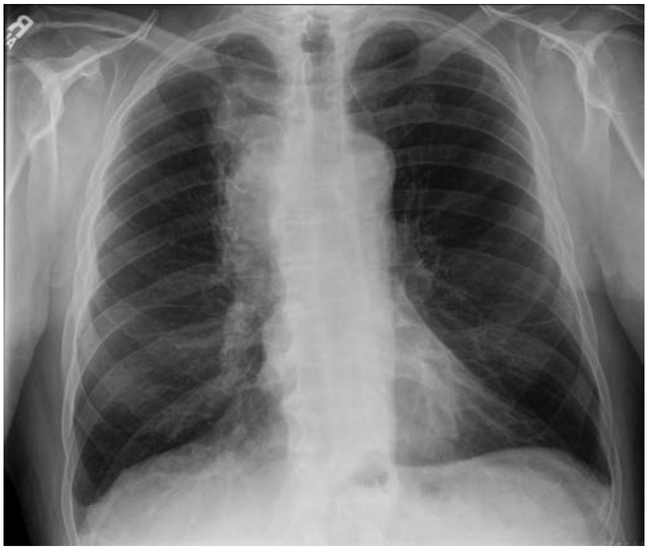

Figure 116-2 Chest radiograph of a patient with SCLC demonstrating increased right paratracheal soft tissue prominence. Note that the right paratracheal line is greater than 3 mm. *(Reproduced with permission from Dr. Matthew J. DeVries, University of Nebraska Medical Center.)*

extensive liver metastases, and isolated elevation of the alkaline phosphatase is seen in patients with bone involvement. In some instances, SCLC infiltrates the bone marrow. In such cases, the CBC reveals pancytopenia with evidence of myelophthisis on the peripheral blood smear (a left shift, nucleated red blood cells, and tear drop cells).

PARANEOPLASTIC PHENOMENA

Certain cancers cause symptoms not attributable to direct tumor invasion or compression. Labeled *paraneoplastic syndromes* in the 1940s, these conditions are primarily due to tumor secretion of functional peptides and hormones (as occurs in endocrine paraneoplastic syndromes [Table 116-3]) or immune cross-reactivity between tumor and normal host tissues (as occurs in neurologic paraneoplastic syndromes [Table 116-4]). Paraneoplastic syndromes may be seen in any type of cancer but historically are most frequently associated with SCLC.

■ Paraneoplastic Endocrinopathy Syndromes

Because paraneoplastic endocrine syndromes are generally due to tumor production of hormones or peptides that lead to metabolic derangements, successful treatment of the underlying tumor often improves these conditions. These disorders are typically detected after a cancer diagnosis. Development of a paraneoplastic endocrine syndrome does not necessarily correlate with cancer stage or prognosis.[103]

Syndrome of Inappropriate Antidiuretic Hormone Secretion

SIADH is characterized by hypo-osmotic, euvolemic hyponatremia. Although it affects only 1% to 2% of all patients with cancer, SCLC accounts for most of these cases, with approximately 10% to 45% of all patients with SCLC developing SIADH.[104] In SIADH, tumor cells produce ADH (also known as arginine vasopressin or vasopressin) and atrial natriuretic peptide.[105,106]

The symptoms of SIADH depend on the degree and rapidity of onset of hyponatremia. Mild symptoms include headache, memory difficulties, and weakness. More severe symptoms (altered mental status, seizures, coma, respiratory collapse, death) may be seen with serum sodium levels less than 125 mEq/L, especially if developing within 48 h.[107] If hyponatremia develops over a longer time period, neurologic complications may not develop.

The time course of hyponatremia also impacts treatment. With symptomatic hyponatremia developing within 48 h, the serum sodium level may be raised 1 to 2 mEq/L/h and usually no more than 8 to 10 mEq/L in the first 24 h. With chronic hyponatremia, due to the brain generating endogenous osmoles to minimize intracellular swelling, rapid correction may lead to water egress, brain dehydration, and central pontine and extrapontine myelinolysis. This condition, which may be irreversible, features lethargy, dysarthria, spastic

quadriparesis, and pseudobulbar palsy. Accordingly, a correction goal of 0.5 to 1.0 mEq/L is recommended for these patients.[104,107]

Successful treatment of the underlying tumor (which is frequently attainable given the chemosensitivity of SCLC) may normalize sodium levels in days to weeks.[104] In the short term, free water restriction (usually <1000 mL/d) along with adequate dietary protein and sodium (with the use of salt tablets if needed) may be implemented. In many instances, administration of standard intravenous fluids may exacerbate SIADH. Normal (0.9%) saline has an osmolality of 308 mOsm/kg, which is often less than urine osmolality in SIADH. Thus, normal saline infusion will result in free water retention and worsening of the hyponatremia. By contrast, hypertonic (3%) saline has an osmolality of 1026 mOsm/kg, which almost always exceeds that of the urine. The primary pharmacologic treatment of SIADH is demeclocycline (usually given at a dose of 300–600 mg per day, but can be increased to 1200 mg per day), an antibacterial agent that interferes with the renal response to ADH. In patients on demeclocycline responding to chemotherapy, careful monitoring is required to ensure against overcorrection and resulting hypernatremia.

TABLE 116-3 Selected Paraneoplastic Endocrine Syndromes Occurring in Small Cell Lung Cancer

Syndrome	Presentation/Symptoms	Laboratory Values	Management/ Treatment[a]
SIADH	Gait disturbances, falls, headache, nausea, fatigue, muscle cramps, anorexia, confusion, lethargy, seizures, respiratory depression, coma	Hyponatremia Mild = serum sodium 130–134 mmol/L Moderate = serum sodium 125–129 mmol/L Severe = serum sodium <125 mmol/L Increased urine osmolality (>100 mOsm/kg in the context of euvolemic hyponatremia)	Fluid restriction (and encourage adequate salt and protein intake) Discontinuation of offending drugs Demeclocycline Vasopressin-receptor antagonists Conivaptan Tolvaptan Hypertonic (3%) saline *(if acute onset)*
Cushing syndrome	Muscular weakness, peripheral edema, hypertension, weight gain	Hypokalemia typically <3.0 mmol/L Elevated baseline serum cortisol >800 nmol/L Normal to elevated midnight serum ACTH (not suppressed with dexamethasone) >100 ng/L	Ketoconazole Octreotide Aminoglutethimide Metyrapone Mitotane Etomidate Mifepristone

[a] *In addition to treating the underlying malignancy.*

TABLE 116-4 Selected Paraneoplastic Neurologic Syndromes Occurring in Small Cell Lung Cancer

Syndrome	Clinical Presentation	Associated Antibodies	Additional Diagnostic Studies	Management/ Treatment
Limbic encephalitis (LE)	Mood changes, hallucinations, memory loss, seizures, less commonly hypothalamic symptoms (hyperthermia, somnolence, endocrine dysfunction); onset over days to months	anti-Hu (ANNA-1) anti-CRMP5 (anti-CV2) anti-Ma anti-amphiphysin	**EEG** epileptic foci in temporal lobe(s); focal or generalized slow activity **FDG-PET** increased metabolism in temporal lobe(s) **MRI** hyperintensity in medial temporal lobe(s) **CSF** pleocytosis, elevated protein, elevated IgG, oligoclonal bands	IVIG Corticosteroids Plasma exchange Cyclophosphamide Rituximab
Paraneoplastic cerebellar degeneration (PCD)	Ataxia, diplopia, dysphagia/dysarthria; prodrome of dizziness, nausea, vomiting	anti-Hu (ANNA-1) anti-Yo anti-CRMP5 (anti-CV2) anti-Ma anti-Tr anti-Ri anti-VGCC anti-mGluR1	**FDG-PET** increased metabolism (early stage) and then decreased metabolism (late stage) in cerebellum **MRI** cerebellar atrophy (late stage)	IVIG Corticosteroids Plasma exchange Cyclophosphamide Rituximab
Lambert–Eaton myasthenic syndrome (LEMS)	Lower extremity proximal muscle weakness, fatigue, diaphragmatic weakness, bulbar symptoms (usually milder than in myasthenia gravis); later in course, autonomic symptoms (ptosis, impotence, dry mouth) in most patients	anti-VGCC (P/Q type)	**EMG** low compound muscle action potential amplitude; decremental response with low-rate stimulation but incremental response with high-rate stimulation	3,4-Diaminopyridine (DAP) Guanidine Pyridostigmine Corticosteroids Azathioprine IVIG Plasma exchange
Subacute (peripheral) sensory neuropathy	Paresthesias/pain (typically upper extremities before lower) followed by ataxia; multifocal/asymmetric distribution; all sensory modalities decreased but especially deep sensation/pseudoathetosis of hands; deep tendon reflexes decreased/absent; onset over weeks to months	anti-Hu (ANNA-1) anti-CRMP5 (anti-CV2) anti-amphiphysin	**NCS** reduced/absent sensory nerve action potentials **CSF** pleocytosis, high IgG, oligoclonal bands	Corticosteroids Cyclophosphamide IVIG Plasma exchange
Autonomic neuropathy	Panautonomic neuropathy, often subacute (weeks) onset, involving sympathetic, parasympathetic, and enteric systems: orthostatic hypotension, GI dysfunction, dry eyes/mouth, bowel/bladder dysfunction, altered pupillary light reflexes, loss of sinus arrhythmia *Chronic gastrointestinal pseudo-obstruction* *(CGP):* Constipation, nausea/vomiting, dysphagia, weight loss, abdominal distension	anti-Hu (ANNA-1) anti-CV2 (CRMP5) anti-nAchR anti-amphiphysin	**Abdominal x-ray/barium studies/ CT** GI dilatation but no mechanical obstruction (for CGP) **Esophageal manometry** achalasia or spasms (for CGP)	*For orthostatic hypotension:* Water, salt intake Fludrocortisone Midodrine Caffeine *For pseudo-obstruction:* Neostigmine

ANNA, antineuronal nuclear antibody; CRMP, Collapsin Response Mediator Proteins; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; EMG, electromyography; FDG-PET, fluorodeoxyglucose positron emission tomography; IVIG, intravenous immunoglobulin; mGluR1, metabotropic glutamate receptor subtype 1; MRI, magnetic resonance imaging; nAchR, nicotinic acetylcholine receptor; NCS, nerve conduction study; VGCC, voltage-gated calcium channel.

Cushing Syndrome

Approximately 5% to 10% of cases of Cushing syndrome (hypercortisolism) are paraneoplastic, and 50% to 60% of these paraneoplastic cases occur with neuroendocrine lung tumors (SCLC and bronchial carcinoids).[108] Paraneoplastic Cushing syndrome is due to tumor secretion of adrenocorticotropic hormone (ACTH) or corticotropin-releasing factor (CRF). In turn, this results in adrenocortical hyperplasia and release of cortisol. Clinical features include hypertension, hypokalemic metabolic alkalosis, hyperglycemia, edema, and muscle weakness. Compared to Cushing disease (i.e., hypercortisolism due to a pituitary adenoma) onset is often more abrupt and weight gain with centripetal fat distribution is less common.

Ectopic (i.e., paraneoplastic) Cushing syndrome is distinguished from a pituitary source by failure to respond to high-dose dexamethasone suppression. For this test, 2 mg of dexamethasone is administered orally every 6 h for 72 h. Levels of urine 17-hydroxycorticosteroid (an inactive product of cortisol metabolism) are measured at 9:00 A.M. and midnight of days 2 and 3 of the test. The test is considered positive if 17-hydroxycorticosteroid levels are reduced by 50% or more. Due to the distinct biochemical profile of paraneoplastic Cushing syndrome, inferior petrosal sinus sampling (to rule out a pituitary etiology) is generally not required.[108]

Therapy includes treatment of the underlying tumor and agents that inhibit steroid production. These include ketoconazole, mitotane, metyrapone, and aminoglutethimide. Ketoconazole is usually the best tolerated of these options, despite nausea, hepatotoxicity, and potential for drug–drug interactions. Supportive care includes antihypertensive agents and diuretics, with careful monitoring of serum potassium. Adrenalectomy may be considered when medical therapy is not successful.

Other Paraneoplastic Endocrine Syndromes

Although paraneoplastic hypercalcemia can be seen with several malignancies (including squamous NSCLC, breast, renal, and lymphoma), it is extremely unusual in patients with SCLC, even among cases with skeletal involvement. Similarly, tumor-associated hypoglycemia, a rare paraneoplastic phenomenon occurring most commonly in sarcomas, mesothelioma, and gastrointestinal cancers, also is unusual in SCLC.

■ Paraneoplastic Neurologic Syndromes

Immune cross-reactivity between tumor cells and components of the nervous system gives rise to paraneoplastic neurologic syndromes. Onconeural antibodies are produced by a patient in response to a developing cancer. Due to antigenic similarity, these onconeural antibodies and associated T lymphocytes inadvertently attack the nervous system as well.[109] Although paraneoplastic neurologic syndromes occur in less than 1% of cancer patients overall, they are seen in up to 5% of patients with SCLC.[110] The potential for immune cross-reactivity with SCLC is apparent through its immunophenotypic profile. CD56, which is positive in the majority of SCLC cases, is also known as neural cell adhesion molecule (NCAM).

In direct contrast to paraneoplastic endocrine syndromes, more than 80% of cases of paraneoplastic neurologic syndromes are detected prior to a cancer diagnosis.[103] Because most patients diagnosed with an apparent paraneoplastic neurologic syndrome will not have known cancer at the time, screening for an underlying tumor is indicated. This process includes complete history and physical examination, as well as imaging studies. If chest, abdomen, and pelvic CT scans are negative, FDG-PET or combined PET-CT may identify the underlying tumor, particularly in the case of an early central SCLC, which may be difficult to identify anatomically amid surrounding mediastinal structures.[111]

Because tumor cells do not directly produce the causative agents (i.e., onconeural antibodies) and because these antibodies may cause permanent neuronal damage, successful cancer treatment does not necessarily result in neurologic improvement. Immunosuppressive therapy—including corticosteroids, other agents, intravenous gamma globulin, and plasma exchange—is a principal component of therapy.

Establishing a diagnosis of a paraneoplastic neurologic syndrome may require imaging, serologies, electroencephalography, electromyography, nerve conduction studies, and cerebrospinal fluid (CSF) analysis for signs of inflammation. Onconeural antibodies lack both sensitivity and specificity, as up to 30% of patients with apparent paraneoplastic neurologic syndromes do not have detectable antibodies and well-defined onconeural antibodies may be detected in individuals with no neurologic illness.[112]

The impact of these conditions on prognosis is complex and multifactorial. Development of a paraneoplastic neurologic syndrome may result in diagnosis of a cancer at an otherwise clinically occult and highly treatable stage. Conversely, the syndrome itself may cause substantial morbidity, independent of the underlying malignancy. Finally, onconeural antibodies may indicate an antitumor immunologic effect; patients with SCLC who have anti-Hu antibodies are more likely to have complete response to therapy and have longer survival than patients without anti-Hu antibodies.[113] While such observations raise the question whether treatment of paraneoplastic neurologic syndromes with immune modulation could lead to cancer progression, this hypothetical scenario has not been reported clinically.[103]

The autoimmune etiology of these paraneoplastic syndromes raises the hypothetical concern that immunotherapy therapy might increase the incidence or severity of these conditions. However, in phase 3 clinical trials, the addition of immune checkpoint inhibitors to platinum-etoposide chemotherapy did not result in increased autoimmune paraneoplastic syndromes, and rates of immune-related adverse events overall were comparable to those in NSCLC and other oncology patient populations.[114,115]

In SCLC, well-described paraneoplastic neurologic syndromes include limbic encephalitis (LE), cerebellar degeneration, Lambert–Eaton myasthenic syndrome (LEMS), subacute (peripheral) sensory neuropathy, optic neuropathy, and autonomic neuropathy.

Limbic Encephalitis

LE features mood changes, hallucinations, memory loss, seizures, and less commonly hypothalamic symptoms (hyperthermia, somnolence, endocrine dysfunction), with onset over days to months. In SCLC, which accounts for 40% to 50% of LE cases, the associated antibody is usually anti-Hu (also known as antineuronal nuclear antibody 1 [ANNA-1]). Characteristic findings may also be seen on electroencephalogram, MRI, and CSF analysis.[116]

Paraneoplastic Cerebellar Degeneration

Paraneoplastic cerebellar degeneration (PCD), manifesting with ataxia, dysarthria, and diplopia, is seen with SCLC (incidence approximately 2%), as well as with gynecologic malignancies and lymphomas. Antibodies that react against cytoplasmic proteins of cerebellar Purkinje cells are often found in these patients. One such antibody, anti-Yo, attacks the cdr2 proteins in the Purkinje cells. Treatment may include steroids, plasmapheresis, and chemotherapy.

Lambert-Eaton Myasthenic Syndrome

LEMS is a result of IgG autoantibodies directed against presynaptic P/Q-type voltage-gated calcium channels. These antibodies are estimated to occur in 5% of patients with SCLC. Clinically, the syndrome presents with proximal muscle weakness, usually in the lower extremities, occasional autonomic dysfunction, and rarely with cranial nerve symptoms. As contrasted with patients with myasthenia gravis, strength *improves* with serial effort, and the weakness associated with LEMS improves over the course of the day. Plasma exchange and intravenous immunoglobulin can provide short-term benefit, whereas 3,4-diaminopyridine (which enhances the release of acetylcholine from presynaptic terminals), prednisone, and azathioprine can provide limited long-term benefit. Some patients who respond to chemotherapy have resolution of the neurologic abnormalities.

Subacute Peripheral Sensory Neuronopathy

With onset over weeks to months, this syndrome initially features paresthesias and pain (typically multifocal, asymmetric, with upper extremities involved before lower), followed by ataxia. Nerve conduction studies demonstrate reduced or absent sensory nerve action potentials. A number of onconeural antibodies, including anti-Hu, may be seen. Lung tumors (principally SCLC) account for 70% to 80% of cases.

Optic Neuropathy

Paraneoplastic optic neuropathy (PON) also has been reported in association with SCLC. The most common presentation is painless visual loss in association with optic disc edema. It may occur in isolation or along with other neurologic syndromes (often neuropathic disorders, limbic encephalitis, or cerebellar degeneration). Many PON patients have antibodies to collapsin response mediator protein 5 (CRMP-5 or anti-CV2), often in conjunction with other paraneoplastic autoantibodies. Clinical improvement has been described with treatment of the underlying cancer and with steroids.[117]

Autonomic Neuropathy

Paraneoplastic autonomic neuropathy typically has a subacute onset over weeks and may involve sympathetic, parasympathetic, and enteric systems.[118,119] Symptoms include orthostatic hypotension, gastrointestinal dysfunction (pseudo-obstruction), and dry eyes and mouth. A number of onconeural antibodies, including anti-Hu and anti-CRMP5 (anti-CV2), may be detected.[120] Other findings suggestive of this condition are loss of sinus arrhythmia (naturally occurring variation in heart rate that occurs during a breathing cycle) on ECG, GI dilation without obstruction on abdominal imaging, and achalasia or spasms on esophageal manometry. Supportive care may include fludrocortisones, midodrine, caffeine, and neostigmine (for pseudo-obstruction).[121]

EXTRAPULMONARY SMALL-CELL CARCINOMA

The knowledge that small cell cancers can arise from tissues other than the lungs has existed since 1930.[122] Extrapulmonary small-cell cancer (EPSCC) remains relatively rare, accounting for <5% of diagnosed small-cell cancers.[123] EPSCC can arise from a variety of primary sites, including the female genital tract (commonly the uterine cervix), the genitourinary organs (primarily bladder and prostate), the head and neck, the gastrointestinal tract, and breast.[124,125]

Staging of EPSCC is similar to that of SCLC. LS is defined as disease confined to the primary site and regional lymph nodes. Any spread beyond the regional lymph nodes is ES disease. It is recommended to perform the same staging evaluation on these patients as in those with SCLC.

Due to the rarity of this entity, the optimal treatment of EPSCC is not clearly defined. Most case series are from single institutions and include EPSCC from a variety of primary sites. In general, the treatment approaches have been adapted from those utilized in SCLC. Surgery has been shown to be curative in selected patients with organ-confined disease. Unfortunately, as with SCLC, EPSCC is often characterized by early metastasis and a fairly aggressive course. Combined chemotherapy and radiation can be utilized for LS disease. ES EPSCC responds to platinum-based chemotherapies in approximately 75% of the cases, but these responses are typically short-lived. In a large retrospective single institution review from Australia, those EPSCC patients with LS disease had a median survival of 1.4 years and a 1-year survival rate of 63%, while those with ES stage disease had median and 1-year survivals of 0.7 years and 24%, respectively.[125] In their cohort, patients with a primary lesion in the female genital tract or the head and neck had superior outcomes when compared with other primary sites. Given the recent approval of immune checkpoint inhibitors given with platinum-based chemotherapy in ES SCLC (see “Immunotherapy,” below), it is reasonable to utilize a similar approach in ES EPSCC.

PROGNOSTIC FACTORS

A variety of pretreatment factors have been reported to have value in predicting therapeutic outcomes for patients with SCLC. Since the aggressiveness of therapy may depend on this perceived outcome, it is important to determine before treatment how a patient is likely to do. The strongest prognostic factors for SCLC are stage of disease (limited vs. extensive) and performance status at presentation. The importance of stage has already been mentioned. ES patients have a lower chance of achieving a complete response to chemotherapy and a much shorter survival than those with LS disease. The performance status or ability of the patient to carry out normal daily activities has a profound effect on both the ability to tolerate chemotherapy and the efficacy of the drugs that are administered (Table 116-5). In general, SCLC patients with a poor performance status have a lower chance of response to chemotherapy, a higher probability of experiencing clinical toxicity, and a worse overall survival.[126–128] However, as opposed to NSCLC patients, poor performance status does not automatically exclude SCLC patients from receiving aggressive treatment. Occasionally, SCLC patients with significant functional impairment can experience improvement with chemotherapy.

Beyond stage and performance status, for treatment-naïve SCLC the clinical features that impact prognosis are presence of a paraneoplastic syndrome, continued use of tobacco, and serum LDH. As mentioned above, LEMS is the most common paraneoplastic neurologic syndrome, developing in 3% to 4% of SCLC patients,[129–131] and in both retrospective and prospective studies LEMS correlates with a marked and significant increase in overall survival.[130,132–134] The only serum marker consistently shown to be of prognostic value in SCLC is the serum concentration of LDH, a nonspecific marker of cell turnover and pulmonary inflammation. Baseline LDH is elevated in 33% to 57% of all SCLC patients and in as many as 85% of patients with ES disease. In a contemporary population of 397 SCLC patients treated from 2004 to 2008, LDH proved to be a strong prognostic marker independent of stage and performance status.[136] In this study, median overall survival was 12 months versus 18 months for LS patients with elevated and normal LDH, respectively; it was 7 months versus 12 months for ES patients with elevated versus normal values. Finally, in addition to its primary role in SCLC tumorigenesis, continued cigarette smoking after diagnosis is an adverse prognostic factor. In a study of 284 patients with LS SCLC treated from 1997 to 2008 at the Mayo Clinic, smoking cessation was at least as significant as performance status, reducing risk of death by 45%.[136]

Treatment-naïve SCLC is remarkably sensitive to chemotherapy—so much so that there was initial optimism that cure could be achieved by escalating drug combinations and regimen dosages, as with some lymphomas.[137] First-line therapy with etoposide-platinum with or without atezolizumab has an overall response rate of 50% to 70%,[138] approximately twice that of first-line therapy for NSCLC.[139] However, relapse is nearly inevitable, at which point

TABLE 116-5 Performance Status Scales

KARNOFSKY			ECOG	
Able to carry on normal activity and to work; no special care needed	100	Normal no complaints; no evidence of disease	0	Fully active, able to carry on all predisease performance without restriction
	90	Able to carry on normal activity; minor signs or symptoms of disease	1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, e.g., light house work, office work
	80	Normal activity with effort; some signs or symptoms of disease		
Unable to work; able to live at home and care for most personal needs, varying amount of assistance needed	70	Cares for self; unable to carry on normal activity or to do active work	2	Ambulatory and capable of all self-care but unable to carry out any work activities. Up and about more than 50% of waking hours
	60	Requires occasional assistance, but is able to care for most of his personal needs		
	50	Requires considerable assistance and frequent medical care	3	Capable of only limited self-care, confined to bed or chair more than 50% of waking hours
Unable to care for self; requires equivalent of institutional or hospital care; disease may be progressing rapidly	40	Disabled; requires special care and assistance		
	30	Severely disabled; hospital admission is indicated although death not imminent	4	Completely disabled. Cannot carry on any self-care. Totally confined to bed or chair
	20	Very sick; hospital admission necessary; active supportive treatment necessary		
	10	Moribund; fatal processes progressing rapidly		
	0	Dead	5	Dead

Data from Schag CC, Heinrich RL, Ganz PA. Karnofsky performance status revisted: reliability, validity, and guidelines. J Clin Oncology. 1984;2(3):187–193; Oken MM, Creech RH, Tormey DC, et al. Toxicity and response criteria of the Eastern Cooperative Oncology Group. Am J Clin Oncol. 1982;5(6):649–655.

SCLC often becomes resistant to further DNA damaging agents; response rates in the second line plummet to approximately 20%, and benefit is brief (~3 months). Following relapse, the strongest known prognostic factor is the duration of response to first-line therapy—significantly stronger than performance status. Disease progression within 90 days of etoposide-platinum portends a dismal outcome (15% response rate, 5.5-month survival) regardless of regimen.[140] Consequently, relapsed SCLC can be reasonably divided into platinum-sensitive versus platinum-resistant disease.

TREATMENT

The roles of surgery, chemotherapy, and radiation in the treatment of SCLC are considered below. In addition, special circumstances, including treatment in the elderly and in those with poor performance status, are discussed.

■ Surgery

Surgery was abandoned as a standard treatment modality for the majority of patients with SCLC in the 1970s following the publication of the results of a trial by the British Research Medical Council randomizing patients with LS disease to single-modality treatment with radiation or surgery. Although outcomes were poor in both treatment arms, the 5- and 10-year survival rates were significantly inferior with surgery.[141] A subsequent Lung Cancer Study Group trial also failed to demonstrate a benefit to surgery when compared with radiation in 340 LS patients following induction chemotherapy.[142] A legitimate criticism of these trials is that patients were inadequately staged when compared with modern standards. In addition, in both trials, only a small fraction of eligible patients had clinical stage I and II disease, which are the groups theoretically most likely to benefit from resection.

Over the past decade, there has been a renewed interest in surgery as a potential treatment modality for highly selected patients with VLS SCLC. A number of primarily retrospective single institution series have reported outcomes with surgery followed by adjuvant chemotherapy (and sometimes radiation) in patients with VLS SCLC. In patients with pathologic stage I disease, the 5-year survival ranged from 40% to 86%.[143–145] In addition, analyses of the Surveillance, Epidemiology, and End Results (SEER) database and the National Cancer Database have shown improved outcomes for those patients with VLS SCLC who are treated with surgery.[94,146,147] Unfortunately, interpretation of these retrospective series and database reviews is hampered by inherent selection bias as well as by the heterogeneity of adjuvant treatment (chemotherapy and radiation) utilized.

Current guidelines suggest that surgical resection should be considered only in patients with clinical stage I (T1 or T2, N0, M0) SCLC and with adequate cardiac and pulmonary function to tolerate a thoracotomy. Patients should undergo rigorous staging, including invasive evaluation for mediastinal nodal disease as well as extensive radiographic assessment for distant metastases. Following complete resection, it is recommended that patients without nodal metastases receive adjuvant chemotherapy and that those with nodal metastases receive concurrent chemotherapy and radiation. Prophylactic cranial irradiation (PCI) can also be considered in selected patients (see "Prophylactic Cranial Irradiation," below). At most centers, fewer than 5% of SCLC patients (primarily those who cancers were discovered incidentally) are considered candidates for a surgical approach.[143]

■ Chemotherapy

Chemotherapy for SCLC can be considered with regard to first-line and second-line regimens.

First-Line Chemotherapy

In contrast to NSCLC, SCLC is classically associated with exquisite chemosensitivity, which may reflect its rapid doubling time and high growth fraction. In reality, the difference in treatment outcomes is modest with comparable median survivals in SCLC and NSCLC following chemotherapy for metastatic disease. Numerous chemotherapeutic agents have demonstrated activity in SCLC (Table 116-6). Untreated, patients with SCLC rarely survive more than a few months. Chemotherapy markedly prolongs survival compared to best supportive care.[148] In LS disease, chemotherapy combined with thoracic radiation achieves a response in 80% to 90% of patients, and a complete response in the range of 40% to 60%. In LS disease, median survival in treated patients is 15 to 20 months, with 5-year survival rates of 10% to 13%. In ES disease, the response rate is 60% to 80%, with a complete response rate around 15% to 35%. The median survival for ES patients treated with chemotherapy remains 7 to 9 months, with few long-term survivors. Patients with bulky or ES disease may be considered at risk for tumor lysis syndrome, although this event is quite rare in clinical practice. Prophylaxis against this complication, which generally includes hydration and allopurinol, may be considered.[149] It should also be noted that systemic chemotherapy frequently yields intracranial responses in patients with brain metastases, with response rates ranging from 27% to 85%.[150,151]

The earliest treatments for SCLC included alkylating agents, such as nitrogen mustard and subsequently cyclophosphamide, given as monotherapy. As responses to single agents were rare, the focus changed to combinations of drugs, each with independent activity against SCLC. When given in combination, these drugs had synergistic activity and lowered the likelihood of complete tumor resistance. Until the mid-1980s the combination of cyclophosphamide, doxorubicin (Adriamycin), and vincristine (CAV) was commonly used as first-line therapy. For the past three decades, platinum-based regimens have become the most frequently used combinations. A meta-analysis of 19 randomized trials encompassing more than 4000 cases demonstrated an increase in response rates and decrease in risk of death for patients receiving cisplatin-containing chemotherapy.[152]

Currently, the two-drug regimen of cisplatin and etoposide is considered the standard of care for SCLC chemotherapy. In randomized trials, this combination appears to be at least as effective as CAV and has less toxicity.[153,154] The cisplatin-etoposide regimen is typically given over 3 days (cisplatin on day 1, etoposide on days 1–3) every 3 weeks for four to six cycles. Modifications to the cisplatin-etoposide regimen have included the substitution of carboplatin for cisplatin, replacing etoposide (a topoisomerase II inhibitor) with irinotecan or topotecan (topoisomerase I inhibitors), adding other agents, increasing dose intensity, and prolonging the duration of chemotherapy.

TABLE 116-6 Chemotherapeutic and Immunotherapeutic Agents with Activity in Small Cell Lung Cancer

Chemotherapeutic Agents
Platinum compounds (cisplatin, carboplatin)
Podophyllotoxins (etoposide, teniposide)
Camptothecins (irinotecan, topotecan)
Alkylating agents (ifosfamide, cyclophosphamide, lurbinectedin)
Anthracyclines (doxorubicin, epirubicin, amrubicin)
Taxanes (paclitaxel, docetaxel)
Vinca alkaloids (vincristine, vinorelbine)
Nitrosoureas (lomustine [CCNU])
Antimetabolites (methotrexate, gemcitabine)
Immunotherapeutic Agents
Check point inhibitors (atezolizumab, durvalumab, nivolumab, ipilimumab, pembrolizumab)

Carboplatin has a more favorable toxicity profile than cisplatin, with less nephrotoxicity, ototoxicity, neurotoxicity, and emetogenicity. Because pre- and posthydration are not required, its administration is also more convenient (typically 45 min for carboplatin vs. 4–6 h for cisplatin, including hydration). In a randomized trial comparing the two agents, cisplatin demonstrated slightly higher overall and complete response rates than did carboplatin: overall response 64% versus 50%; complete response 16% versus 10%. However, there was no significant difference in overall survival.[155] Based on a more favorable toxicity profile, most clinicians in the United States employ carboplatin–etoposide for the treatment of ES SCLC, with cisplatin–etoposide preferred for the treatment of LS SCLC due to the possibility of a higher response rate.

Cisplatin plus irinotecan has been compared to cisplatin plus etoposide in a number of clinical trials. In a Japanese study, the irinotecan-containing arm demonstrated a significantly higher response rate (84% vs. 68%), longer median survival (12.8 months vs. 9.4 months), and higher 2-year survival rate (19.5% vs. 5.2%).[156] However, three larger studies performed in Western populations did not confirm these findings, raising the possibility of pharmacogenomic differences between the populations.[157–159]

Three- and four-drug regimens, in which agents such as paclitaxel, ifosfamide, cyclophosphamide, and epirubicin are added to etoposide-platinum, have yielded mixed results. Some studies have demonstrated higher response rates and modest prolongation of survival, but often at the cost of increased toxicity, including higher rates of treatment-related mortality in some instances.[160–162] Administration of non–cross-resistant regimens such as etoposide-platinum and CAV in alternating or sequential fashion has not consistently demonstrated a survival benefit.[163] Several studies have explored increasing chemotherapy dose intensity via dose escalation, shortening the interval between cycles, and providing hematopoietic support through growth factor administration or stem cell transplantation.[164–66] None of these approaches has demonstrated consistent benefit.

Maintenance chemotherapy, which has emerged as a new standard of care for advanced NSCLC, has also been studied in SCLC. In these trials, patients with nonprogressing disease after four cycles of combination induction therapy immediately proceed to maintenance monotherapy with agents such as topotecan or etoposide.[167,168] Individual trials have not demonstrated a significant increase in overall survival. Although a meta-analysis has suggested a modest survival advantage,[169] few if any oncologists employ this approach in the management of SCLC.

Based on the extant literature, it appears the optimal therapy for a majority of SCLC patients is etoposide-platinum, with the addition of thoracic radiotherapy for those with LS disease (see below). Treatment beyond four to six cycles is unwarranted in the first-line setting. There is little support for the use of dose intensification or so-called "dose-dense" therapy as a course of routine treatment.

Immunotherapy

FDA approvals for immune checkpoint inhibitor therapy alone or in combination with conventional chemotherapy represent one of the few recent advances in the medical treatment of SCLC. These monoclonal antibodies, which target programmed death 1 (PD-1), PD-1 ligand (PDL-1), or cytotoxic T-lymphocyte antigen 4 (CTLA4) "release the brakes" on the immune system, resulting in enhanced antitumor immunity. Immune checkpoint inhibitors are now approved for numerous common solid tumors and lymphoma, with an estimated 45% of patients with advanced malignancies eligible for these treatments.[170]

Given the promising effects of immune checkpoint inhibitors in NSCLC one might anticipate even greater efficacy in SCLC. Patients with SCLC tend to have greater smoking history, which may be associated with heightened tumor mutational burden and, in turn, antigenicity.[171] Furthermore, the heightened incidence of autoimmune paraneoplastic phenomena reflecting immune cross-reactivity between SCLC and normal tissues suggests an underlying antitumor immune response against SCLC.

While immune checkpoint inhibitors have indeed improved outcomes in this disease, their relative benefit appears less than that achieved in non–small-cell lung cancer. The addition of the anti-PD1 agent atezolizumab to carboplatin–etoposide as first-line treatment of extensive-stage SCLC resulted in an improvement in medial overall survival from 10.3 months to 12.3 months (hazard ratio [HR], 0.70; 95% confidence interval [CI], 0.54–0.91; $p = 0.007$).[114] Similarly, the addition of the anti-PDL1 agent durvalumab to first-line platinum–etoposide increased median overall survival from 10.3 to 13.0 months (HR, 0.73; 95% CI, 0.59–0.91; $p = 0.005$).[115] With both of these regimens, if patients are continuing to benefit from and tolerate treatment after four cycles of combination therapy, the immune checkpoint inhibitor is continued as maintenance monotherapy until disease progression or intolerable toxicity. Unfortunately, compared to NSCLC, it is less clear whether a proportion of patients treated with these new regimens will truly be long-term survivors or potentially cured.

Notably, despite the high mutational burden of SCLC, relatively few cases are PD-L1 positive, a biomarker associated with checkpoint inhibitor efficacy in NSCLC. Specifically, in SCLC, approximately 20% of cases have tumor PD-L1 expression ≥1%, compared to approximately 70% of NSCLC cases.[172] This observation serves as a reminder that these biomarker populations have only partial overlap, with 20% of high-mutational-burden tumors having high PD-L1 expression and 30% of PD-L1–high tumors also having high mutational burden.[173]

Due to low prevalence and limited predictive capacity, PD-L1 is not used as a clinical biomarker for treatment decisions in SCLC, although it may be used in NSCLC for consideration of first-line checkpoint inhibitor monotherapy and combination immunotherapy regimens. Indeed, in SCLC, tumor mutational burden may be a more useful predictive biomarker for anti-PD1 or combined anti-CTLA4 regimens. Radiographic response to nivolumab (anti-PD1) is 5% in low tumor mutation burden, versus 21% in high-mutation-burden cases. Similarly, with combination nivolumab and ipilimumab (anti-CTLA4), response rates are 22% and 46% for low and high mutation burden, respectively.[173] To date, however, tumor mutation burden is not a formally approved biomarker for routine clinical care in SCLC or any other malignancies treated with checkpoint inhibitors.

Second-Line Chemotherapy

Although the majority of SCLC patients treated with first-line chemotherapy demonstrate tumor response, most eventually relapse. Response to first-line therapy tends to be brief, with a median duration of 6 to 8 months. Along with performance status and tumor extent (i.e., limited vs. extensive), the time to relapse after first-line therapy is among the most important prognostic factors in SCLC.[126] The timing of relapse also has implications when considering further treatment options. Patients who relapse greater than 6 months after completion of first-line therapy are often re-treated with etoposide–platinum. Patients with earlier disease progression can be categorized as *sensitive relapse* (tumor progression >90 days after last day of initial treatment), *resistant relapse* (tumor progression ≤90 days after last day of initial treatment), or *refractory* (tumor progression during initial therapy or unresponsiveness to initial therapy). For patients with sensitive relapse, response rates to second-line chemotherapy are 30% to 40%, and median survival is approximately 6 months. For those with resistant relapse or refractory disease, responses occur in less than 10% of cases.

For many years in the United States, the topoisomerase I inhibitor topotecan was the only FDA-approved drug for second-line treatment for SCLC. Oral and intravenous topotecan formulations used as a single agent exhibit response rates of 11% to 37%.[174–176] These responses are rarely durable, with median time to progression of 12 to 13 weeks and resultant median survival of 6 to 7 months. In 2020, the alkylator lurbinectedin was granted accelerated FDA approval based on a single-arm phase 2 trial in relapsed/refractory SCLC that reported a tumor response rate of 35% and a median response duration of 5.3 months.[177] Comparative trials against topotecan are underway to determine if lurbinectedin offers a survival advantage.

■ Radiation Therapy

The role of radiation in treatment of SCLC may be considered with respect to thoracic radiation and prophylactic cranial irradiation.

Thoracic Radiation Therapy

SCLC is a malignancy that is sensitive to radiation. Thoracic radiation therapy (TRT) as a single modality results in an objective tumor response rate of 75% in LS disease, and may cure as many as 5% of these patients.[141] Initial clinical trials combining TRT with chemotherapy yielded mixed results. For the most part, these early trials demonstrated a decrease in local recurrence but no clear survival benefit. However, two meta-analyses published in 1992 reported a statistically significant 5% improvement in overall survival with the addition of radiation to chemotherapy in SCLC patients with LS disease.[178,179] These reports established concurrent chemotherapy and radiation as the standard of care for fit patients with LS SCLC. Significant questions remained regarding the optimal timing, dose, and fractionation of radiation. A number of trials have evaluated early (typically <30 days after initiation of chemotherapy) versus late radiation and have yielded conflicting results. Both a subsequent meta-analysis and systematic review of the available data concluded that early radiation resulted in a small but significant improvement in overall survival and have established early TRT as the preferred approach for patients with LS disease.[180,181]

The optimal fractionation and dose of TRT also are unknown. The Eastern Cooperative Oncology Group conducted a randomized trial in LS SCLC patients comparing twice-daily TRT to 45 Gy with the prior standard of once-daily TRT to 45 Gy. Both treatment arms received standard etoposide–platinum chemotherapy. They reported a significantly improved median (23 vs. 19 months) and 5-year survival (27% vs. 11%) favoring twice-daily TRT.[182] Despite these results, this strategy has not been widely adopted, presumably due to the inconvenience of administering twice-daily TRT. A criticism of this trial is that the radiobiologic dose of 45 Gy twice daily is significantly higher than once daily to 45 Gy, and therefore daily radiation to a higher dose may produce comparable results. However, a European randomized phase 3 trial (CONVERT) failed to demonstrate a survival advantage for once-daily radiation to 66 Gy over twice daily to 45 Gy, although numeric outcomes and toxicity between the two arms were similar.[183] A second randomized trial comparing twice-daily to 45 Gy with once-daily to 70 Gy is ongoing. At present, both strategies (twice daily to 45 Gy and once daily to 60–70 Gy) are utilized in clinical practice.

Consolidative chest irradiation is beneficial in selected patients with ES SCLC who respond to initial chemotherapy. Trials demonstrate decreased progression in the chest as well as improved survival in some patients, although the patients most likely to benefit are those with residual chest disease after chemotherapy and limited extrathoracic metastases.[184,185] Of note, the safety of administering chest radiation in patients receiving immune checkpoint inhibitor therapy (see above) has not been evaluated in any prospective trial. Radiation also plays a palliative role in ES disease, and can be used for symptomatic control in bony, pulmonary, and brain metastases.

Prophylactic Cranial Irradiation

As detailed earlier, the brain is a frequent site of metastatic spread in SCLC. Some 10% to 18% of patients have brain involvement at presentation, and 60% to 80% of SCLC patients who survive at least 2 years will develop brain metastases.[95,96,186] The prevailing assumption is that micrometastases in the brain are relatively protected from systemic chemotherapy by the blood–brain barrier. Given these facts, a number of randomized trials evaluated PCI in LS SCLC patients who had a complete or near-complete response with chemotherapy and TRT. These studies reproducibly showed significant reductions in the incidence of brain metastases with PCI but had conflicting results regarding the impact of PCI on overall survival. In 1999, an individual patient data meta-analysis of all available randomized trials reported a 5.4% increase in overall survival at 3 years (15.3% vs. 20.7%) favoring PCI. PCI also reduced the cumulative risk of brain metastases at 3 years from 58.6% to 33.3%.[187]

PCI in ES SCLC similarly reduces brain metastases, but the impact on survival is debated. In a European trial, patients with ES disease who experienced at least a partial response to chemotherapy were randomized to PCI or observation. The primary endpoint, symptomatic brain metastases, was reduced from 41.3% in the observation arm to 16.8% with PCI. Median survival (6.7 months vs. 5.4 months) and 1-year survival (27.1% and 13.3%), both secondary endpoints, were significantly improved with PCI.[188] A criticism of this trial is that it did not perform routine surveillance for asymptomatic brain metastases. In a trial from Japan, ES SCLC patients who responded to initial chemotherapy were randomized to PCI or routine MRI surveillance for brain metastases (allowing for early treatment of asymptomatic metastases). No difference in overall survival was seen between the two groups.[189]

Current guidelines recommend consideration of PCI for all LS patients with a good performance status who have attained a complete or near-complete response after chemotherapy and radiation. In ES SCLC patients who respond to initial chemotherapy, routine MRI surveillance or PCI are acceptable options. Concern has been raised about long-term neurocognitive impairment from PCI, which includes potential effects on communication and memory that may be dose dependent.[190,191] Therefore, before undergoing PCI, patients should be counseled regarding the expected risks and benefits of this intervention. In addition, strategies such as hippocampal sparing PCI and the use of memantine are considerations to mitigate these effects.

■ Treatment in the Elderly and Patients with a Poor Performance Status

In most patients with metastatic solid tumors and a poor performance status, chemotherapy is felt to be of limited benefit given the high likelihood of severe toxicity and the low chance of a significant durable tumor response. As noted earlier, given the relative chemosensitivity of SCLC, an impaired performance status does not necessarily preclude treatment. Some SCLC patients with functional impairment can experience significant tumor response and resultant modest improvements in their performance status after treatment with chemotherapy.

Similarly, age should not be the sole criterion by which treatment decisions in SCLC are based. In recent series, the median age at diagnosis in SCLC is >65 years and approximately 40% of patients are ≥70 years.[94] Clearly, elderly (typically defined as >70 years old) patients with SCLC will be encountered frequently in clinical practice. Treatment of these patients is complicated by underlying comorbidities as well as decreased organ function that may lead to poor tolerance of treatment. Unfortunately, the elderly are typically underrepresented in clinical trials in SCLC, and therefore there is little definitive prospective evidence on the appropriate management of this group. The available information suggests that elderly patients who are able to tolerate standard treatment for SCLC fare as well as their younger counterparts.[192] In addition, prospective randomized trials of "less intensive treatment" in those felt to be at risk for excess toxicity from standard therapy found inferior survival and palliation on the "less intensive" treatment arms.[193] Current recommendations are to consider comorbidities and functional capacity, rather than age alone, when making treatment recommendations for these patients.

COMPLICATIONS

Both radiotherapy and chemotherapy cause side effects specific to the agent used. Irradiation can have early (esophagitis, pneumonitis, superficial skin burns) and late (pulmonary fibrosis, late cardiac disease, myelitis) toxicities. Chemotherapy toxicities depend on the specific regimen used, but they generally include alopecia, nausea and vomiting, and myelosuppression. Bone marrow suppression can lead to life-threatening bleeding episodes (from thrombocytopenia), but more commonly it is associated with neutropenic fevers, and occasionally fatal infections. Published series in SCLC patients have demonstrated that episodes of febrile neutropenia occur in roughly 30% of treated patients, documented infection in 5% to 15%, and fatal infection in 7%. Prevention of infection in patients treated with chemotherapy with or without irradiation has received significant attention. Measures have included prophylactic use of antibiotics and granulocyte colony-stimulating factor (GCSF). Recently, a large, randomized trial showed that GCSF in addition to chemotherapy led to a reduction of the number of episodes of neutropenic fever and documented infections. Many oncologists do not agree that this is a cost-effective measure, however.

Immune checkpoint inhibitors convey risk of immune-related adverse events. These autoimmune toxicities may affect almost any organ system, including skin, thyroid, lungs, pituitary, GI tract, liver, kidney, joints, and, in rare cases, heart or central nervous system. These toxicities may be severe or potentially permanent, and they may occur at almost any point during (or occasionally even after) immunotherapy.

The estimated incidence of immune-related pulmonary toxicities varies widely, from approximately 5% to 20% of treated patients.[194,195] Clinical manifestations are nonspecific and include cough, dyspnea, hypoxia, chest discomfort, and fever. Radiographic features may include ground-glass opacities, consolidations, interlobar septal thickening, pleural effusions, and lymphadenopathy, findings that may overlap with infection, other toxicities (e.g., radiation pneumonitis), or disease progression.[196] Bronchoalveolar lavage may show a lymphocyte-predominant differential, and bronchoscopic biopsy may demonstrate cellular interstitial pneumonitis, organizing pneumonia, or diffuse alveolar damage.[197] Management of immune-related pulmonary events and other autoimmune toxicities centers on immunosuppression, most commonly corticosteroids. For moderate to severe cases, steroid tapers over several weeks may be required. Occasionally, other immunosuppressants such as mycophenolate, anti-TNF antibodies, or IVIG may be required. Unlike chemotherapy, there is no role for dose reduction with immune checkpoint inhibitors. These agents are either given at full dose, temporarily withheld, or permanently discontinued.

Given that the majority of patients with SCLC are older and have extensive smoking histories, it is not surprising that cardiovascular, cerebrovascular, and pulmonary diseases are extremely common in this population. Thus, a large portion of long-term survivors of SCLC succumb to these other diseases. Up to one-third of all long-term surviving patients, especially those who continue to smoke, have recurrence of their SCLC or, more rarely, develop a new SCLC. Other aerodigestive cancers, particularly NSCLC, are extremely common, leading some investigators to propose trials of chemoprevention agents in long-term survivors of SCLC. Finally, patients with SCLC have an increased risk of developing a hematologic malignancy. Secondary leukemias are believed to be related to treatment, especially if chemotherapy with alkylating agents was employed. Some of these posttreatment leukemias have also shown a deletion of chromosome 3, suggesting an underlying predisposition or common ancestor cell to both cancers, instead of a secondary leukemia arising from alkylating chemotherapy–induced genetic damage. Overall, 2-year survivors of SCLC face a 3.5-fold increased risk of a second cancer (mostly NSCLC) compared with the general population. The risk of a second lung cancer is increased 13-fold among those patients who received TRT and 7-fold among those who did not undergo radiation, with ongoing smoking further escalating risk.[198] Accordingly, long-term surveillance is mandatory in these otherwise cured patients.

CONCLUSION

SCLC is distinct from the other three major histologic varieties of pulmonary malignancies, which tend to behave similarly and are lumped together under the generic rubric "NSCLC." It is biologically more active, secreting multiple hormones and neural markers, resulting in a number of paraneoplastic syndromes. It is thought of as a systemic disease, and treatment nearly always includes chemotherapy and, more recently in ES patients, immune checkpoint inhibitors. Although the tumor is highly responsive to initial therapy, and survival is significantly prolonged with systemic treatment, the complete eradication of SCLC remains a relatively rare event. Long-term survivors are subject to a host of cardiopulmonary conditions, as well as second malignancies and recurrence of their SCLC. In the era of tumor genomic profiling and molecularly targeted therapies, there is hope that new insights into tumor biology and novel therapies may show promise in the treatment of this aggressive and often fatal cancer.

CHAPTER 117

Uncommon Tumors of the Lung

Karen Rodriguez
Gerald F. Abbott

INTRODUCTION

Although lung cancer is the most common primary pulmonary neoplasm, a variety of uncommon or rare primary pulmonary tumors may occur, including both benign and malignant entities. This chapter reviews the most frequently encountered uncommon tumors of the lung.

BENIGN TUMORS

Benign lung tumors include hamartomas, chondromas, papillomas, and inflammatory myofibroblastic tumors, each of which is discussed below.

■ Hamartoma

Pulmonary hamartoma is the most common benign pulmonary neoplasm, accounting for 6% of all solitary pulmonary nodules. Hamartomas are composed of varying amounts of at least two mesenchymal tissues, such as cartilage, fat, bone, connective tissue, and smooth muscle, in combination with entrapped respiratory epithelium.[1–6] Most hamartomas occur as solitary nodules in the periphery of the lung (Fig. 117-1), and affected patients are asymptomatic. However, approximately 10% of hamartomas may involve the airways and produce symptoms and imaging signs of bronchial obstruction. Affected patients may present with cough, dyspnea, or pneumonia. Hamartomas occur more often in men than women, with a peak incidence in the sixth decade. They should be considered in the imaging diagnosis of pulmonary nodules that exhibit intrinsic fat and calcification on CT.[7–10] MRI in-phase and out-of-phase imaging can also be used to demonstrate the presence of macroscopic fat.[1,12]

Small, slow-growing hamartomas can be managed conservatively. If the diagnosis is uncertain or if larger lesions or endobronchial lesions cause postobstructive findings, then surgical resection is often performed.[13–15]

Multiple hamartomas may occur in Cowden syndrome, an autosomal dominant disorder that may affect multiple organs, including the skin, thyroid gland, and gastrointestinal tract. In addition to its association with benign hamartomas, the syndrome carries an increased risk of breast and thyroid cancers.[16]

Pulmonary chondromas are benign cartilaginous tumors that consist entirely of cartilaginous components that may calcify.[17] Chondromas may be associated with Carney triad, which is defined by the coexistence of extra-adrenal paragangliomas, gastric gastrointestinal stromal tumors (GIST), and pulmonary chondroma and is typically seen in young women.

■ Solitary Papilloma/Papillomatosis

Squamous cell papilloma is a benign papillary tumor that arises from the wall of a mainstem, secondary, or tertiary bronchus as an exophytic “cauliflower-like” growth. The tumor consists of delicate connective tissue fronds formed by arborizing fibrovascular cores covered by stratified squamous epithelium. A solitary papilloma is very rare, accounting for <1% of all pulmonary neoplasms.[18–21] Multiple papillomas may involve the larynx, trachea, bronchial tree, and lung parenchyma as laryngotracheal papillomatosis, also known as recurrent respiratory papillomatosis (RRP).[22–28] Juvenile laryngeal papillomatosis affects children (18 months to 3 years of age) and may remain localized to the larynx or resolve spontaneously. However, in 5% of patients involvement spreads to the trachea and remains limited to that airway.[29,30]

Approximately 1% of patients develop lung disease as papillomatosis spreads to involve the main bronchi and, subsequently, to bronchi, bronchioles, and the alveolar airspaces. Patients with mild involvement may be asymptomatic or present with hoarseness due to laryngeal involvement. Lung involvement typically occurs 10 years after laryngeal disease.

On imaging studies tracheobronchial papillomatosis is manifest as airway wall nodularity that may be sessile or polypoid, with

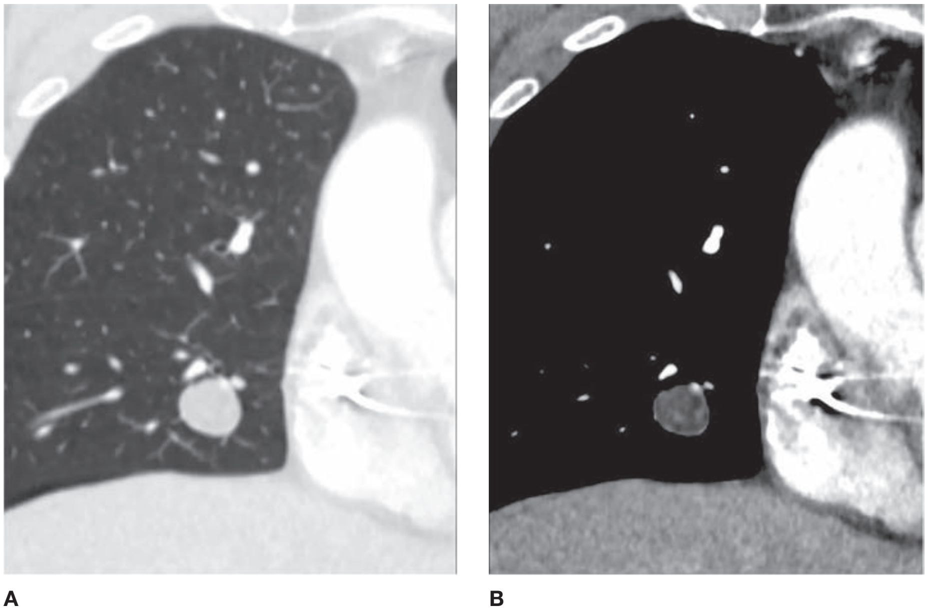

Figure 117-1 Hamartoma. Contrast-enhanced coronal CT images in lung window (**A**) and mediastinal window (**B**) demonstrate a well-circumscribed peripheral pulmonary nodule in the right lower lobe. The mediastinal window image (**B**) reveals macroscopic fat manifesting as low attenuation within the nodule. Most hamartomas occur as peripheral nodules in asymptomatic patients, but 10% occur as central lesions that may be endobronchial and cause obstructive symptoms and imaging findings. The CT demonstration of macroscopic fat within a pulmonary nodule is considered diagnostic of pulmonary hamartoma.

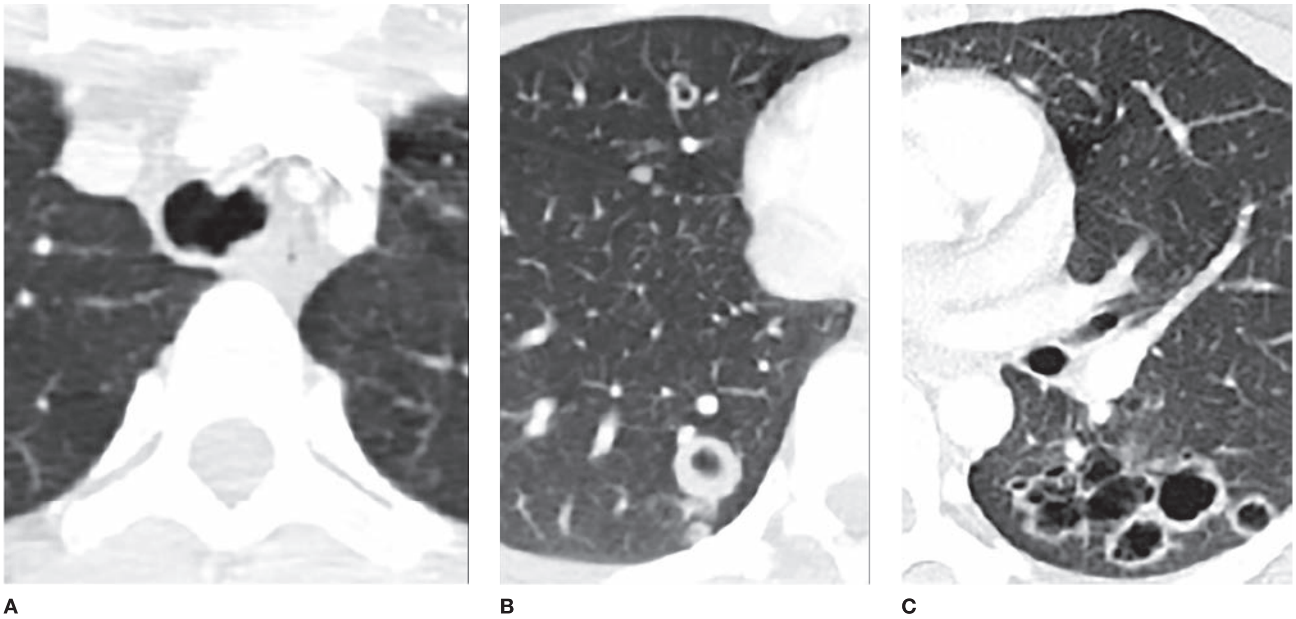

Figure 117-2 Papillomatosis. Composite CT image shows mural nodules in the trachea (**A**), cavitary nodules in the right middle and lower lobes (**B**), and thick-walled cystic lesions in the left lower lobe (**C**). The nodular and cystic lesions demonstrate predominant involvement of the posterior, dorsal aspects of both lungs—a characteristic distribution of lung involvement in tracheobronchial papillomatosis, suggesting that aspiration may play a role in the pathogenesis of papillomatosis.

the upper airways more commonly affected. Multiple pulmonary nodules and masses may evolve into cavitary nodules with irregular walls and subsequent cystic lesions, all of which have a predominantly posterior distribution in both lungs (Fig. 117-2).[22–28] Most nodules are slow growing and benign; however, rapid growth may occur in up to 2% of cases and undergo malignant transformation to squamous cell carcinoma. Multiple risk factors predispose to a higher risk for squamous cell carcinoma, including cigarette smoking, a history of prior radiation exposure, and infection with human papillomavirus (HPV) types 6 and 11.[18]

Solitary papilloma can be managed conservatively. For patients with RRP, surgical resection using laser therapy may be utilized for lesions causing airway obstruction or hoarseness.

Inflammatory Myofibroblastic Tumor

Inflammatory myofibroblastic tumor (IMT) is a spindle cell neoplasm with low malignant potential. It usually occurs in children and young adults and typically manifests as a well-defined mass. Patients are usually symptomatic with nonspecific constitutional symptoms, such as fever and malaise.[31–34] Histologically, IMT consist of spindle cell (myofibroblast) proliferation and inflammatory cells, including plasma cells and lymphocytes, within a background of granulation tissue.[32,33] Tumors are classified based according to varying degrees of mitosis, necrosis, and vascular invasion. Anaplastic lymphoma kinase (ALK) oncogene mutation is seen in up to 60% of IMT. On cross-sectional imaging, IMT typically manifests as a heterogeneously enhancing nodule or mass; central calcification or necrosis may occur (Fig. 117-3). On MRI, IMT may demonstrate T2 hypointensity due to the tumor's fibrous stroma.

IMT often have a good prognosis following complete surgical resection, but incomplete resection may result in recurrence. Chemotherapy along with steroids and radiation therapy are considered when surgical resection is not feasible.

MALIGNANT TUMORS

Uncommon malignant tumors of the lung include bronchial carcinoid (both typical and atypical), adenoid cystic carcinoma, mucoepidermoid carcinoma, lymphoma, and carcinosarcoma, each of which is considered below.

Bronchial Carcinoid (Typical and Atypical Carcinoid)

Bronchial carcinoids are low-grade, malignant neuroendocrine tumors that arise from tracheobronchial Kulchitsky cells.[35–40] The

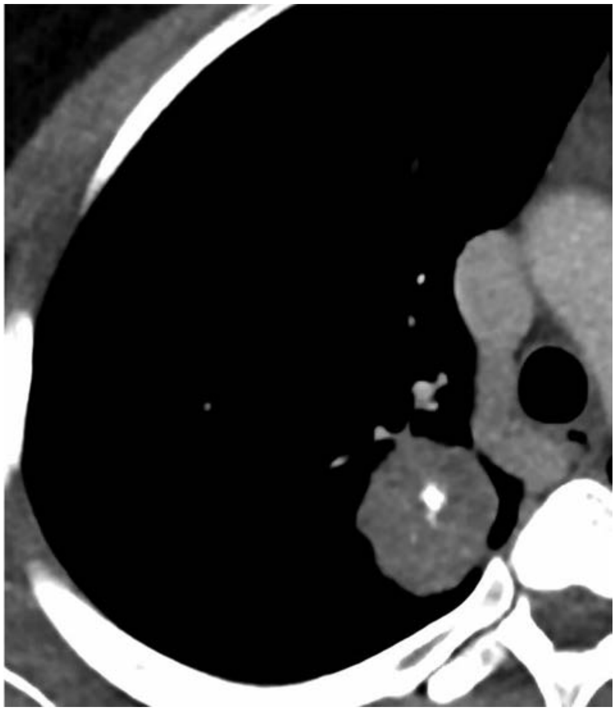

Figure 117-3 Inflammatory myofibroblastic tumor. Axial CT of a 38-year-old nonsmoker demonstrates a peripheral pulmonary nodule with lobulated margins and a focal area of eccentric calcification. Differential diagnostic considerations include bronchial carcinoid tumor, granuloma, and lung cancer.

World Health Organization has classified these tumors based on mitotic activity and necrosis into typical carcinoids (TC) and atypical carcinoids (AC).

Typical carcinoids have rare mitotic figures (<2 mitoses per 10 high-power fields), and necrosis is absent. Atypical carcinoids tend to be larger than typical carcinoids. Atypical carcinoids have increased mitotic activity (2–10 mitoses per 10 high-power fields) and may demonstrate tumor necrosis.[41,42] Carcinoid tumors typically occur in young and middle-aged patients, with a mean age of 55 years and equal female–male distribution. The average age for patients with atypical carcinoids tends to be about a decade older than those with typical carcinoids. Affected patients often complain of cough and may report episodes of hemoptysis.

Some patients may present with postobstructive pneumonia due to air trapping from endobronchial ball-valve obstruction. A rare presentation is a paraneoplastic syndrome, such as Cushing syndrome due to ectopic production of adrenocorticotropic hormone (ACTH), which occurs more often in patients with AC than those with TC. Carcinoid syndrome is rare in cases of bronchial carcinoid tumors, but it has been reported in patient with AC and liver metastases.[43,44]

Macroscopically, bronchial carcinoid tumor typically manifests as a smooth red polypoid endobronchial nodule or mass. Most arise within central bronchi. Microscopically, bronchial carcinoids are characterized by uniform cells separated by a fibrovascular stroma.

Neuroendocrine neoplasms (NE) form a spectrum with varying grades and aggressiveness, ranging from low-grade TC, to intermediate grade AC, and to more aggressive large-cell neuroendocrine carcinoma (LCNEC) and small-cell lung cancer (SCLC). Histologic analysis of NE also demonstrates a spectrum in the number of mitotic figures detected per 10 high-power fields (HPF), ranging from less than 2 in TC to at least 2 in AC, and greater than 10 in NEC and SCLC. AC and TC may not always be reliably distinguished from each other on small biopsy specimens.[41,42]

Typical and atypical carcinoids demonstrate similar features on imaging studies. Most carcinoids occur as a central hilar or perihilar nodule or mass (>3 cm) with 85% in the mainstem, lobar, or segmental bronchi (Fig. 117-4A, B). Bronchial carcinoids may be completely endobronchial, but often they are manifest as an "iceberg" growth pattern, with the bulk of tumor outside of the airway and a smaller endobronchial component within forming the "tip of the iceberg" (Fig. 117-4C, D). Most affected patients present with postobstructive symptoms. Up to 20% of carcinoids may occur as a peripheral, solitary pulmonary nodules, and patients may be asymptomatic.[39,40] On CT, carcinoid tumors may exhibit calcification, typically demonstrate intense enhancement on contrast-enhanced studies, and often reveal their airway relationship and related findings of atelectasis and/or postobstructive pneumonitis (Fig. 117-4E).

Complete surgical resection is the most effective treatment. Recurrence-free survival is common in patients with TC. Tumor histology and nodal status are the main predictors of mortality. Five-year survival rates following complete resection of TC and AC are 87% to 100% and 44% to 77%, respectively.[42] Survival decreases in the presence of nodal metastases. There is no correlation between tumor size and the presence of nodal involvement.

Multiple carcinoid tumorlets or carcinoid tumors are suggestive of diffuse idiopathic pulmonary neuroendocrine cell hyperplasia (DIPNECH). DIPNECH has been described predominantly in older women, typically nonsmokers. CT characteristics include lower lobe–predominant nodules and mosaic attenuation on expiratory imaging. DIPNECH has a generally good prognosis, with very slow growing tumorlets.[45]

■ Adenoid Cystic Carcinoma

Adenoid cystic carcinoma (ACC) is a slow-growing neoplasm that arises from submucosal gland myoepithelial cells.[46–54] ACCs typically arise in the trachea and mainstem bronchi and are the second most common malignant tracheal neoplasms. The average age of affected patients is 30 to 50 years, with equal gender distribution. Patients may present with nonspecific respiratory symptoms, such as dyspnea, cough, and stridor and are often misdiagnosed as having asthma.[47] Microscopically, ACC demonstrates a high nuclear-to-cytoplasmic ratio and an infiltrative pattern of uniform tumor cells. Perineural extension is a histologic hallmark of ACC.[51]

The characteristic imaging features of ACC are annular airway thickening and polypoid or broad-based endoluminal nodules or masses in the trachea or mainstem bronchi (Fig. 117-5).[47] ACCs more frequently involve the distal two-thirds of the trachea. CT demonstrates homogenous soft tissue thickening with variable degrees of airway luminal narrowing. ACC may involve a long tracheal segment due to longitudinal submucosal extension of tumor and may demonstrate local invasion into the adjacent mediastinal fat.[47–50] Some patients present with advanced disease, most commonly mediastinal lymphadenopathy and hematogenous pulmonary nodular metastases.

ACC have a good prognosis following complete resection with end-to-end anastomosis of the trachea; 5- and 10-year survivals are 65% to 100% and 50% to 60%, respectively.[46] Tumors with local invasion of the adjacent mediastinal fat may require extensive resection. Local recurrence or residual disease may respond well to radiation but may pose a risk of tracheoesophageal fistula.

■ Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma (MEC) is less common than ACC; it also arises from bronchial glands in the tracheobronchial tree. MEC affects young patients, typically less than 30 years of age, with an equal gender distribution. These tumors are typically ovoid, endoluminal, well-circumscribed nodules that primarily affect the main or lobar bronchi and much less commonly the trachea. Affected patients usually present with cough and postobstructive pneumonia.[55,56] MECs are classified as low- or high-grade, based on their microscopic features; both display solid collections or sheets of squamous cells. A propensity of mitoses and necrosis characterizes the high-grade MEC. The characteristic imaging features of MEC are a nodule or mass involving the main or lobar bronchi, often accompanied by obstructive atelectasis or pneumonia (Fig. 117-6).

The prognosis for low-grade MEC is usually good; complete resection is curative. High-grade MEC may present with mural invasion and lymph node metastasis.

■ Lymphoma

Lymphoma comprises a diverse group of malignant neoplasms arising from lymphocytes.

Non-Hodgkin lymphoma (NHL) is the most common type of lymphoma (80%–90% of all cases). Hodgkin lymphoma (HL) represents 10% to 20% of all lymphomas.[57] Both NHL and HL frequently involve the chest, most often as lymph node malignancies that primarily involve the mediastinum; however, both may affect the lung with primary or secondary involvement that may be a manifestation of systemic disease.[58]

Primary pulmonary lymphoma (PPL) represents less than 1% of all pulmonary malignancies and is defined as malignant lymphoma originating from pulmonary parenchyma or bronchi, with or without hilar lymph node involvement, in a patient with no evidence of extrathoracic lymphoma for at least 3 months after the initial diagnosis. The most common type of PPL is mucosa-associated lymphoid tissue (MALT) lymphoma (70%–90%), and less commonly diffuse large B-cell lymphoma (DLBCL) and lymphomatoid granulomatosis (LYG).[57] Secondary pulmonary lymphoma (SPL) is more common than PPL and refers to a secondary involvement of the lung from a

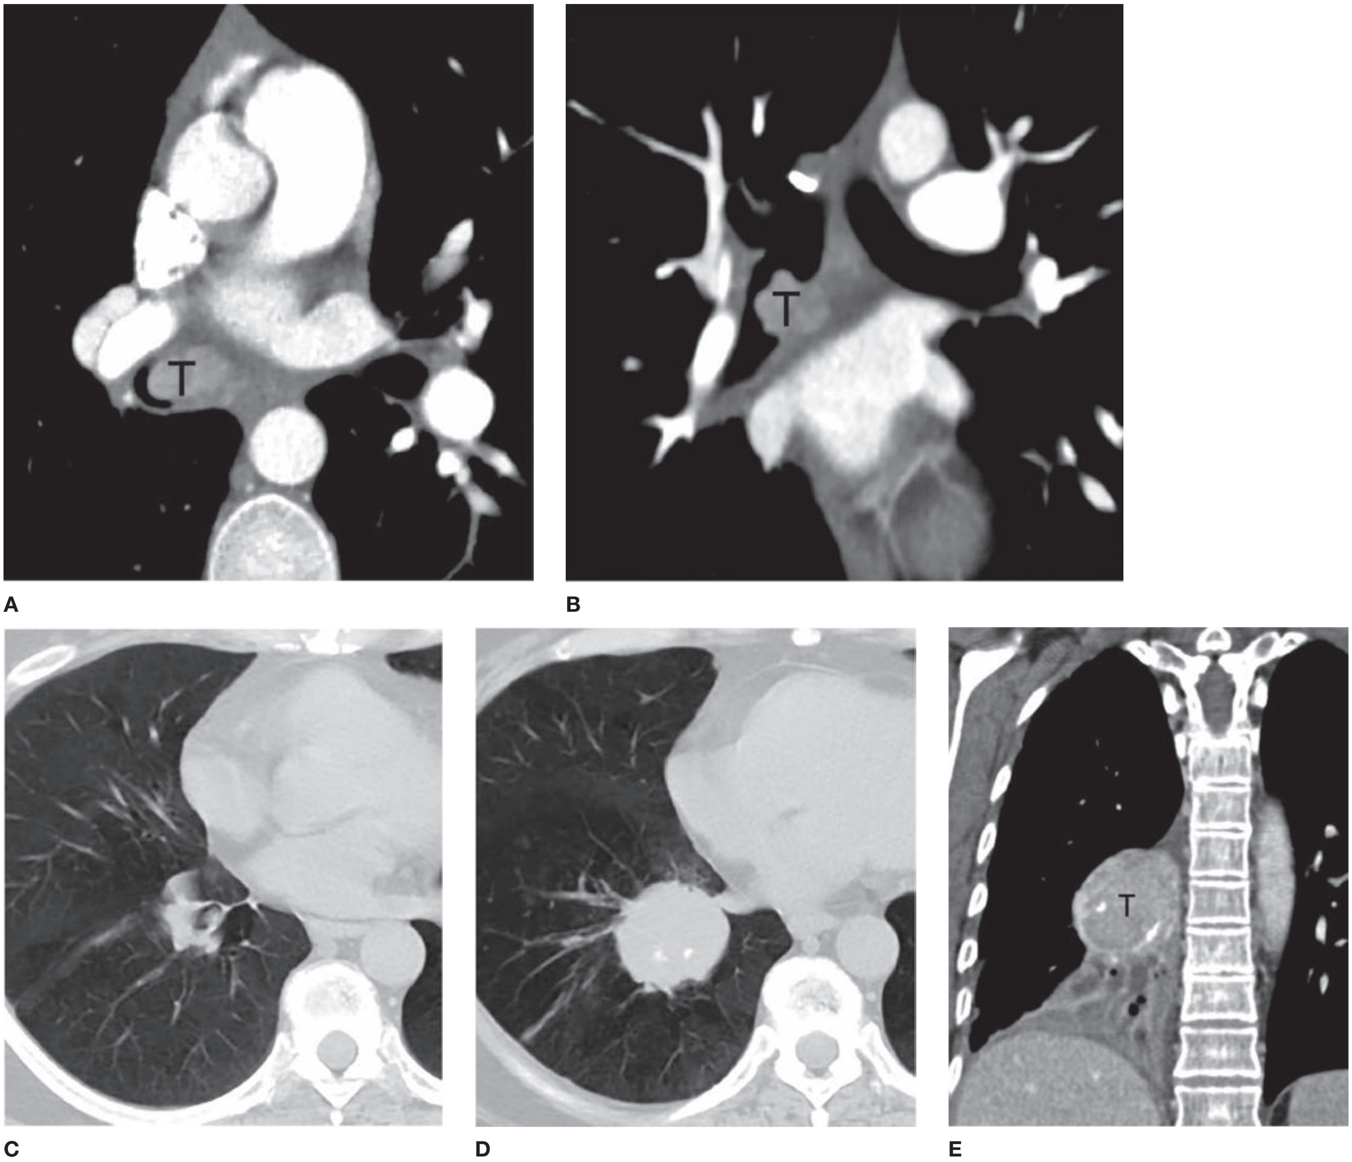

Figure 117-4 Bronchial carcinoid. Composite of axial (**A**) and coronal (**B**) CT images demonstrates an enhancing endobronchial carcinoid tumor (**T**) in the bronchus intermedius with lobulated contours and without distal effects. Bronchial carcinoid tumors typically demonstrate contrast enhancement on CT, likely a manifestation of their underlying fibrovascular stroma. Note the focal penetration of tumor through the medial bronchial wall, a characteristic feature of bronchial carcinoid tumors. Axial CT images demonstrate the characteristic "iceberg" growth pattern of bronchial carcinoid tumors, with the tip of the iceberg manifesting as a focal endobronchial lesion in the right lower-lobe bronchus (**C**) and the bulk of the tumor outside of the airway (**D**). The larger tumor component (**D**) also demonstrates eccentric foci of calcification, a frequent imaging finding in bronchial carcinoid tumors. The imaging features of typical and atypical carcinoid tumors are indistinguishable. That determination is made by pathologists, based on the number of mitotic figures per 10 high-power fields. Coronal CT (**E**) of a bronchial carcinoid involving the right lower-lobe bronchus demonstrates a large central enhancing carcinoid tumor (**T**) that obstructs the airway with resultant lobar atelectasis and distal bronchiectasis with dilated, fluid-filled airways with foci of air. There are eccentric and peripheral areas of calcification within the tumor. Bronchial carcinoid tumors typically involve the central airways and may cause distal atelectasis and pneumonitis.

known extrapulmonary lymphoma. These two origins of pulmonary lymphoma are pathologically distinctive but may share the same mediastinal manifestations with similar imaging features.[58]

In 2016, the World Health Organization published a revised classification scheme that grouped lymphomas by cell type and by their molecular, cytogenetic, and phenotypic characteristics.[59–62]

On chest CT primary malignant lymphoma manifests as bilateral pulmonary nodules or masses that may be focal or multifocal, and unilateral or bilateral, with ill-defined or well-defined borders, and, frequently, air bronchograms (Fig. 117-7A, B). Other imaging manifestations include areas of lobar or segmental consolidation and endobronchial lesions with postobstructive changes. Less common manifestations include miliary pulmonary nodules or a lymphangitic pattern of tumor spread. Direct chest wall invasion also may occur.[58]

Surgery has been suggested as the preferred treatment in cases of localized PPL when complete resection may be achieved. Patients with SPL are typically treated with chemotherapy. Prognosis varies based on the subtype and clinical stage of disease.[57]

■ Carcinosarcoma

Pulmonary carcinosarcoma is a rare tumor that typically occurs in older men (50–80 years old) with a history of heavy cigarette

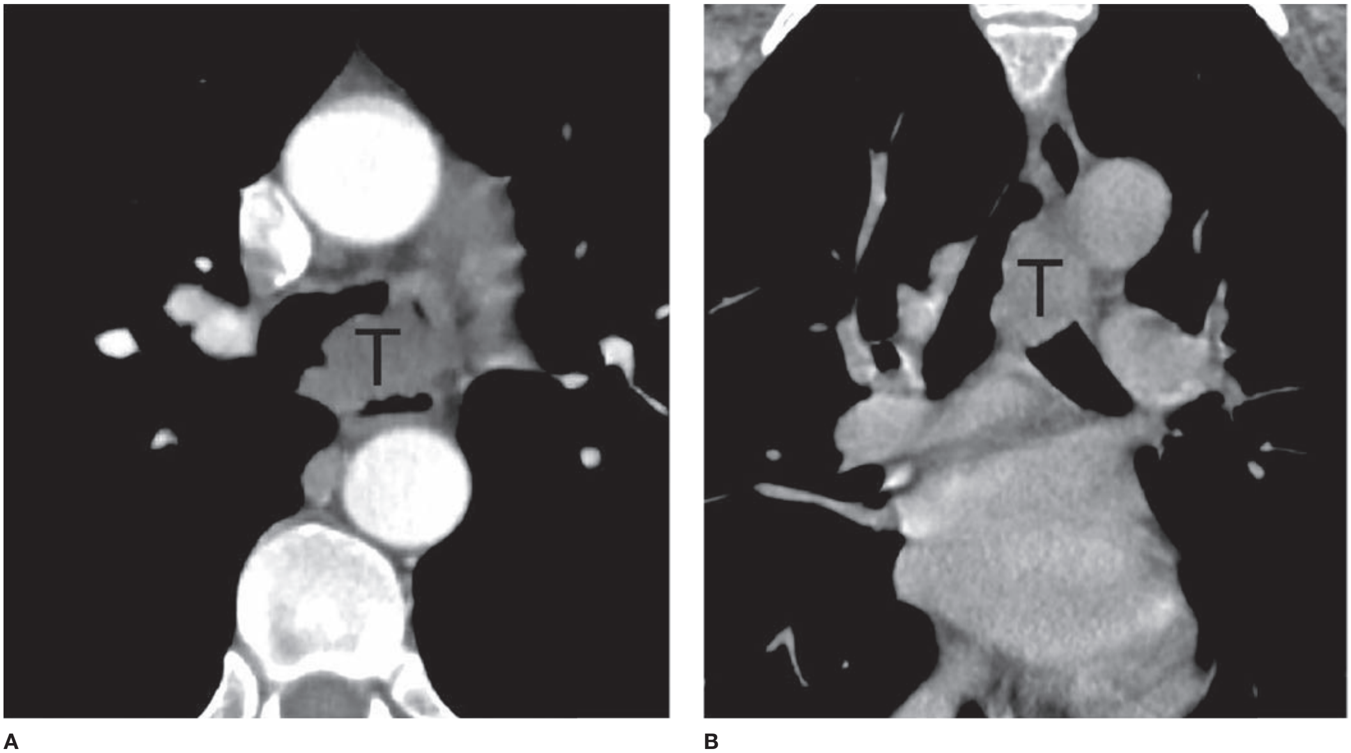

Figure 117-5 Adenoid cystic carcinoma. Composite CT image in the axial **(A)** and coronal **(B)** planes demonstrates an endobronchial tumor **(T)** with nodular and annular mural components involving the distal trachea and proximal left main bronchus. Biopsy revealed an adenoid cystic carcinoma. The combination of nodular and annular growth pattern is characteristic of adenoid cystic carcinoma, but differential diagnostic considerations include squamous-cell carcinoma and mucoepidermoid carcinoma.

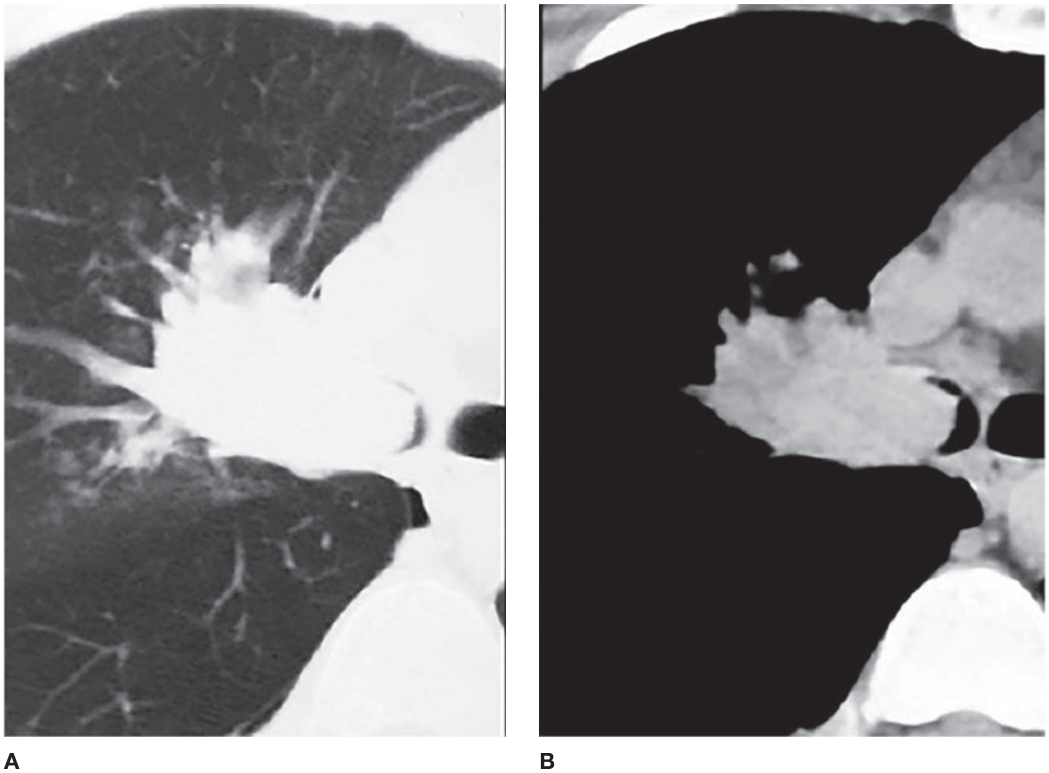

Figure 117-6 Mucoepidermoid carcinoma. Composite of axial CT image shown in both lung window (**A**) and mediastinal window (**B**) demonstrates a mucoepidermoid carcinoma involving the right main and right upper-lobe bronchi with distal patchy ground-glass opacity and several small centrilobular nodules as a manifestation of obstructive pneumonitis. Mucoepidermoid carcinomas affect primarily the lobar and segmental bronchi.

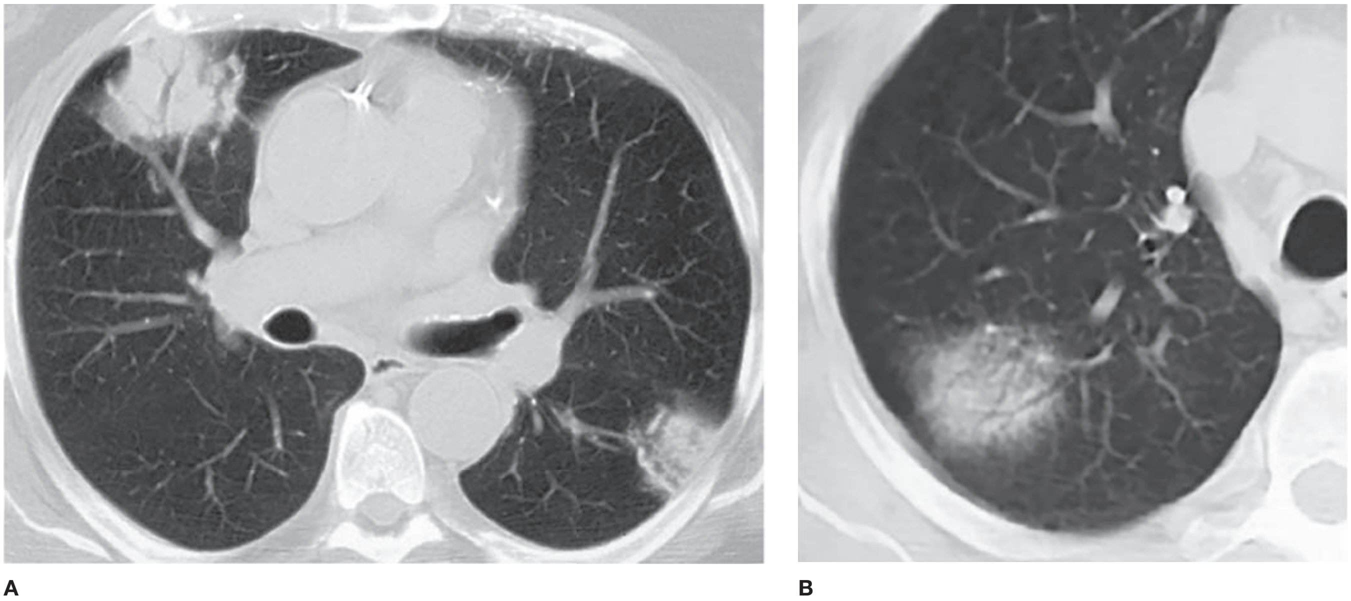

Figure 117-7 Lymphoma. Axial CT images of two patients demonstrate multifocal **(A)** and focal **(B)** pulmonary lymphoma manifesting as rounded consolidative opacities that exhibit air bronchograms, a characteristic appearance of pulmonary lymphoma. Other imaging manifestations include areas of segmental or lobar consolidation and less frequently endobronchial lesions. Chest wall invasion may also occur.

smoking.[63] Carcinosarcomas, often referred to as mixed tumors, are composed of a mixture of epithelial and mesenchymal components that are both malignant. Either of the malignant components may predominate—the carcinomatous (squamous cell carcinoma, adenocarcinoma, or undifferentiated carcinoma) or the sarcomatous (spindle cell, rhabdomyosarcoma, chondrosarcoma, or osteosarcoma).[63]

The characteristic gross pathologic features of carcinosarcoma are a large mass (average diameter 6 cm) with an upper lobe predominance, frequently with associated areas of necrosis and hemorrhage. Direct tumor extension may occur to the pleura, chest wall, and mediastinum.

Microscopically, the carcinomatous elements are often displaced to the tumor periphery, suggesting rapid growth of the central sarcomatous elements that form the bulk of the tumor. Immunohistochemical staining for keratin is positive for both the epithelial and mesenchymal components, suggesting that carcinosarcomas are of a monoclonal epithelial origin that has undergone sarcomatoid metaplasia.

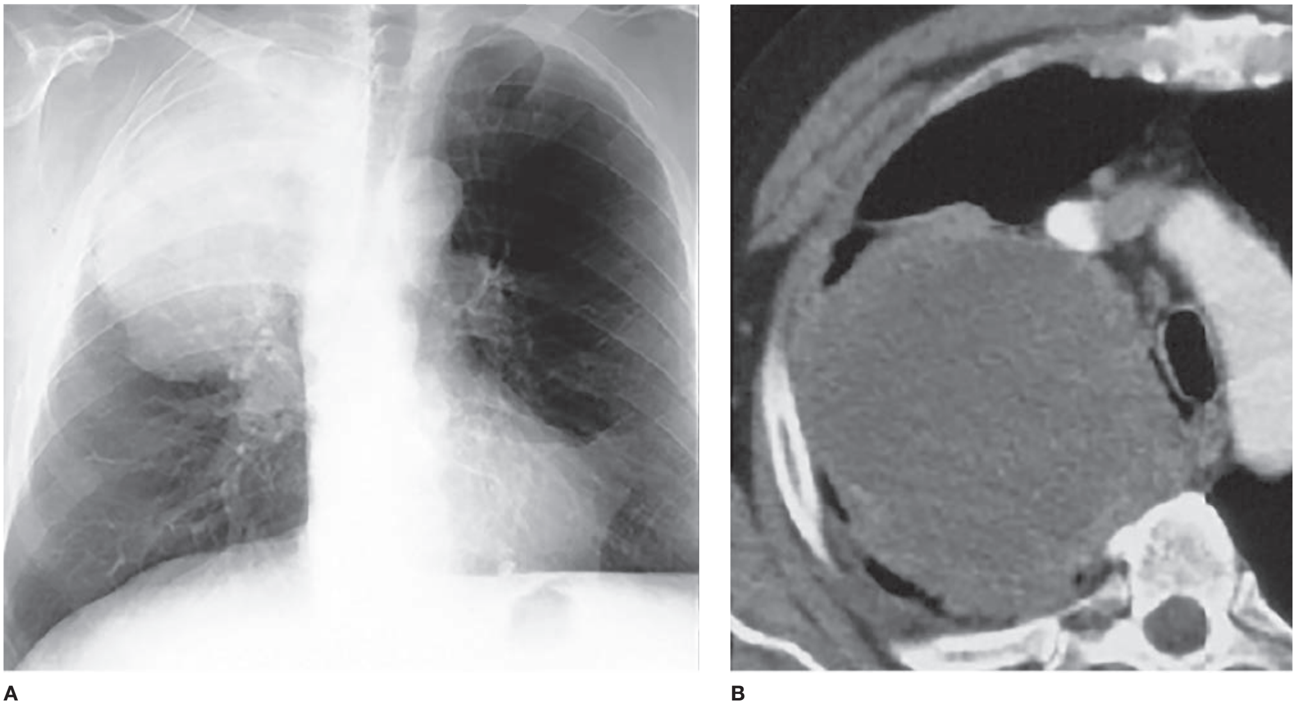

Figure 117-8 Carcinosarcoma. Composite image of PA chest radiograph (**A**) and axial CT (**B**) demonstrate a large in the right upper lobe of an elderly man with a 40-pack-year history of cigarette smoking. The mass abuts the mediastinal and costal pleural surfaces and exhibits heterogeneous low attenuation, suggestive of necrosis. While lung cancer was the most likely diagnosis to consider, histologic evaluation revealed carcinosarcoma.

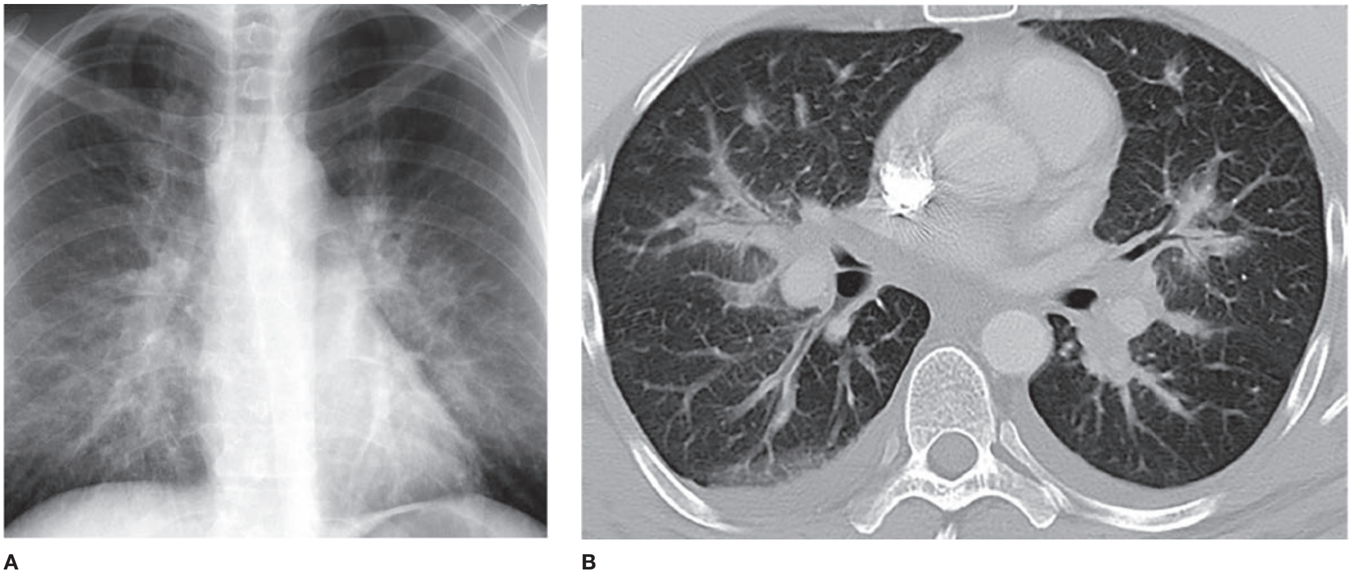

Figure 117-9 Kaposi sarcoma. PA chest radiograph (**A**) of a 38-year-old man with AIDS-KS demonstrates bilateral perihilar and midzone patchy opacities that appear to extend along the bronchovascular structures. Axial chest CT (**B**) reveals indistinct patchy and nodular opacities extending along the bronchovascular structures and within the lung parenchyma. The peribronchovascular opacities have been described as flame-shaped, some with peripheral halos of ground glass opacity. There are additional findings of bilateral pleural effusions and bilateral hilar lymphadenopathy, characteristic findings in Kaposi sarcoma.

On imaging, carcinosarcoma typically manifests as a large mass, predominantly involving an upper lobe, that may manifest signs of mediastinal and/or chest wall invasion, often with associated findings of atelectasis and pneumonia (Fig. 117-8).

Clinically, carcinosarcoma is characterized by aggressive growth, local invasion, widespread metastases, and rapid death.[63]

■ Kaposi Sarcoma

Kaposi sarcoma (KS) is a low-grade mesenchymal neoplasm of blood and lymphatic vessels that is associated with human herpesvirus type 8.[64,65] Four distinct types include iatrogenic KS, endemic KS, classic or Mediterranean KS, and AIDS-KS. AIDS-KS is the most common AIDS-related neoplasm. Affected patients typically present with dyspnea and cough, especially those patients with CD4 lymphocyte counts less than 200 cells/mm^3.

On imaging, AIDS-KS typically manifests as ill-defined nodules in a mid- to lower-zone-predominant pattern, with nodules typically in a symmetric perihilar and peribronchovascular distribution (Fig. 117-9). The consolidative nodules have been described as having a "flame-shaped" appearance, often with a halo of ground-glass opacity.[65] Associated findings of interlobular septal thickening, nodularity along interlobar fissures, lymphadenopathy, and pleural effusions are common. The treatment for AIDS-KS is highly active antiretroviral therapy and chemotherapy.

CHAPTER 118

Extrapulmonary Syndromes Associated with Lung Tumors

Nicholas J. Pastis
Nichole T. Tanner
Gerard A. Silvestri

INTRODUCTION

A wide variety of extrapulmonary syndromes have been reported with lung cancer. This chapter focuses primarily on paraneoplastic syndromes, a heterogeneous group of disorders associated with cancer but not due to direct invasion, obstruction, or metastasis.[1,2] As many paraneoplastic syndromes share similar underlying mechanisms, they may be classified according to the system in which they cause disease (endocrine, hematologic, dermatologic, rheumatologic, or neurologic syndromes). More broadly speaking, they are either hormonally or immunologically based.

Paraneoplastic syndromes affect up to 8% of patients with cancer,[3] and of all malignancies, lung cancer is most commonly associated with these syndromes. The subtype of lung cancer most commonly associated with paraneoplastic syndromes is small-cell lung cancer (SCLC),[4] but some syndromes such as hypertrophic pulmonary osteoarthropathy (HPO) and hypercalcemia are more common in non–small-cell lung cancer (NSCLC).[5]

Endocrine and hematologic syndromes associated with lung tumors are listed in Table 118-1. The endocrine syndromes are characterized by the ectopic production by tumor cells of biologically active peptide hormones that bind to receptors in adjacent or distant organs, giving rise to a clinical syndrome. Hematologic syndromes develop in patients with lung cancer through the production by tumor cells of cytokines that activate progenitor cells in the bone marrow. Neurologic syndromes, such as encephalomyelitis and subacute sensory neuropathy, are caused by the induction of antibodies directed against proteins expressed by the lung cancer cells and directed against antigens present on cells in the nervous system.

In clinical practice, an understanding of the extrapulmonary syndromes is important for several reasons: (1) recognition of a syndrome may serve as a harbinger of an occult malignancy or may signify disease recurrence; (2) the course of the endocrine and hematologic syndromes usually parallels the course of the lung cancer, although the neurologic syndromes frequently do not; and (3) appropriate treatment of the extrapulmonary syndrome often reduces the patient's morbidity and may allow definitive treatment of the cancer. In general, definitive treatment of the underlying tumor is the most effective form of therapy for the paraneoplastic syndromes, so their presence should not preclude treatment of lung cancer with curative intent as most syndromes are reversible once the patient receives treatment.

HYPERCALCEMIA OF MALIGNANCY

Hypercalcemia is commonly seen in cancer patients,[6,7] and lung cancer is the most common solid tumor associated with it, occurring in up to 20% of patients.[8,9] It is overall the most common of the paraneoplastic syndromes. It occurs most frequently in patients with squamous cell lung cancer but is occasionally seen in patients with adenocarcinoma and very rarely in patients with SCLC.[10]

Biology

Etiologic mechanisms for hypercalcemia in patients with lung cancer include tumor secretion of parathyroid hormone–related peptide (PTHrP), tumor production of the active metabolite of vitamin D (calcitriol, also called 1,25-dihydroxyvitamin D_3), and localized osteolytic hypercalcemia due to osteolytic metastasis with release of cytokines including osteoclast activating factors.[6,11] Most cases of hypercalcemia in patients with lung cancer are caused by the ectopic production of PTHrP by tumor cells (referred to as humoral hypercalcemia of malignancy).[12–14] The PTHrP gene expresses three messenger RNAs (mRNAs) that encode three distinct peptides, each differing at the COOH-terminal region (Fig. 118-1). Eight of the first 13 amino acids in PTHrP are homologous with PTH, so similar functional activity is shared between the 2 peptides. PTHrP mRNA and peptides have been demonstrated in cancer cells from patients with lung cancer and hypercalcemia. PTHrP has been shown to bind to PTH receptors in the bone and kidney, which causes increased osteoclastic bone resorption, decreased bone formation, and decreased calciuria, leading to hypercalcemia.[15,16] Levels of 1,25-dihydroxyvitamin D_3 are suppressed in patients with PTHrP-induced hypercalcemia, but are raised in patients with primary hyperparathyroidism. This difference occurs because renal α-hydroxylase activity is low in PTHrP-induced hypercalcemia, unlike primary hyperparathyroidism.[17] PTH production by lung

TABLE 118-1 Endocrine and Hematologic Syndromes Associated with Lung Tumors

Syndrome	Tumor	Proteins/Cytokines
Hypercalcemia of malignancy	Non–small-cell	Parathyroid hormone–related peptide
		Parathormone
Hyponatremia of malignancy	Small-cell	Arginine vasopressin
	Non–small-cell	Atrial natriuretic peptide
Ectopic ACTH syndrome	Small-cell	Adrenocorticotropic hormone
	Carcinoid tumors	Corticotropin-releasing hormone
Acromegaly	Carcinoid tumors	Growth hormone–releasing hormone
	Small-cell	Growth hormone
Carcinoid syndrome	Carcinoid tumors	Serotonin
	Large-cell	
	Small-cell	
Granulocytosis	Non–small-cell	G-CSF
		GM-CSF
		IL-6
Thrombocytosis	Non–small-cell	IL-6
	Small-cell	
Thromboembolism	Non–small-cell	Unknown
	Small-cell	

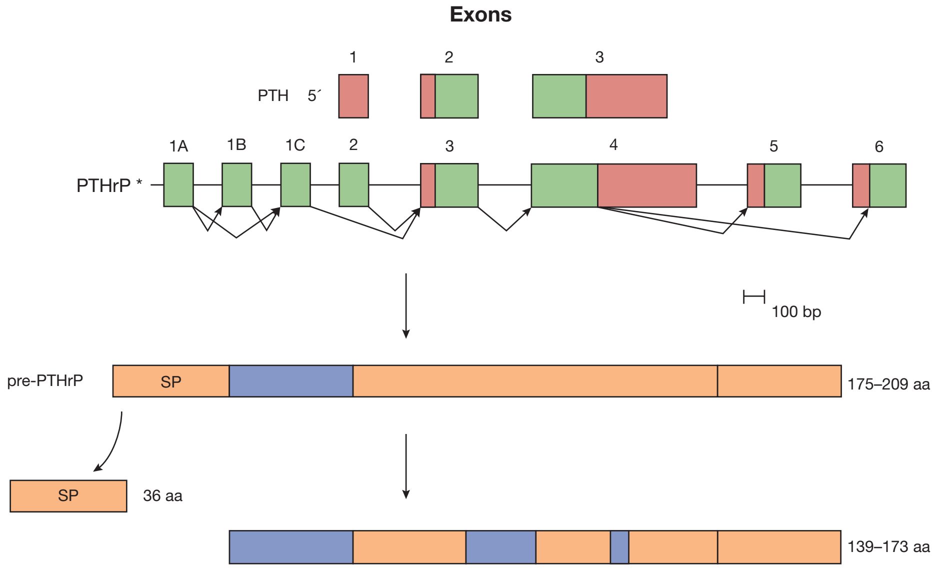

Figure 118-1 Parathyroid hormone and parathyroid hormone–related peptide. The human PTH gene has three exons, which constitute the protein-coding segments. Three exons are represented by 3 boxes for PTH and 8 exons are represented by 8 boxes for PTHrP. The PTHrP gene is more complex, with eight exons. Through alternative splicing, three different isoforms of mRNA can be produced. These isoform mRNAs encode the pre-PTHrP proteins, which vary in size from 175 to 209 amino acids (aa). Thirty-six amino acids are removed from the amino terminal end as the signal peptide. Three different PTHrP molecules are produced, with 139 to 173 aa. The rectangular region at the carboxy terminal represents the different lengths of PTHrP. The N-terminal region (1-34aa) mimics the classic PTH-like function (*purple box on left*). The midregion of the peptide stimulates placental calcium transport (*orange and purple box*). The C-terminal region (107-111 aa) inhibits osteoclast bone resorption (*orange, purple, orange boxes before box at carboxy terminal*).

cancer cells also has been described, but it is a very rare cause of hypercalcemia of malignancy.[18–20] Other factors that cause bone resorption have been identified in the plasma of patients with lung cancer, including transforming growth factor α and a vitamin D metabolite. These are very rare, however, and their causative role in hypercalcemia has not been shown conclusively.

Diagnosis

The early symptoms of hypercalcemia include thirst, malaise, fatigue, anorexia, polyuria, constipation, nausea, and vomiting. As hypercalcemia becomes increasingly severe (>14.0 mg/dL), confusion, lethargy, coma, and death can occur. The demonstration of a suppressed intact parathyroid hormone (iPTH) level and a low or normal calcitriol level along with an increased concentration (>10.5 mg/dL) of calcium in the serum of a patient with NSCLC should suggest this paraneoplastic syndrome. This is in contrast to the findings of elevated iPTH and calcitriol levels in primary hyperparathyroidism, which may occur in up to 10% of patients with cancer. A complete diagnostic evaluation includes measuring serum concentrations of iPTH, PTHrP,[21] 1,25-dihydroxyvitamin D, 25-hydroxyvitamin D, calcium, albumin, magnesium, and phosphorus. Other potential causes of elevated serum calcium also should be excluded. Thiazide diuretics, vitamin D or lithium administration, hyperthyroidism, and sarcoidosis are potential causes.[22] Bone scintiscan should be obtained to exclude bone metastases. An elevated PTHrP level in the absence of bone metastases establishes the diagnosis of humoral hypercalcemia of malignancy caused by ectopic PTHrP.[16,21]

Treatment

As with other paraneoplastic syndromes, treatment of the underlying cancer is the most effective method of treating the humoral hypercalcemia associated with lung cancer. Until this can occur, medical management of hypercalcemia must be considered. If asymptomatic or mildly symptomatic, hypercalcemic patients with calcium levels less than 12 mg/dL (3 mmol/L) do not require immediate treatment. Similarly, a serum calcium level of 12 to 14 mg/dL (3–3.5 mmol/L) may be well tolerated chronically and may not require immediate treatment. However, an acute rise to these concentrations may cause a marked change in sensorium and an oncologic emergency requiring urgent intervention.[23] Patients with a serum calcium concentration greater than 14 mg/dL (3.5 mmol/L) require treatment, regardless of symptoms.[24,25] Treatment includes intravenous normal saline. The addition of furosemide diuresis should not be routine and should occur only after correction of intravascular volume depletion. Loop diuretics may be needed in patients with renal insufficiency or heart failure. Subcutaneous calcitonin has a rapid onset of action and is most useful in severe cases. Bisphosphonates, such as pamidronate, are effective for long-term control of hypercalcemia.[26] In patients in whom bisphosphonates are contraindicated (severe renal impairment), denosumab can be administered. Corticosteroids exert their effect through inhibition of dihydroxyvitamin D_3 synthesis and therefore have less effect in patients with elevated PTHrP. There may be circumstances requiring hemodialysis when serum calcium concentrations are 18 to 20 mg/dL with neurologic symptoms or in severe cases when patients cannot be safely hydrated due to renal insufficiency or heart failure.[27]

Humoral hypercalcemia usually develops in patients with advanced progressive cancer and is associated with a median survival of about 1 month.[28,29] Nonetheless, in some cases, treatment of hypercalcemia serves an important palliative role by improving symptoms and allowing patients to be discharged from the hospital. Hypercalcemia is often a sign of metastatic non–small-cell lung cancer, so early palliative care consultation is recommended.[27]

HYPONATREMIA OF MALIGNANCY

Hyponatremia is a frequent complication in patients with cancer. It occurs at presentation in approximately 15% of patients with SCLC and 1% of patients with NSCLC.[30] The ectopic production of arginine vasopressin (AVP) by cancer cells plays a causal role in the majority of cases.[30] This form of hyponatremia is recognized

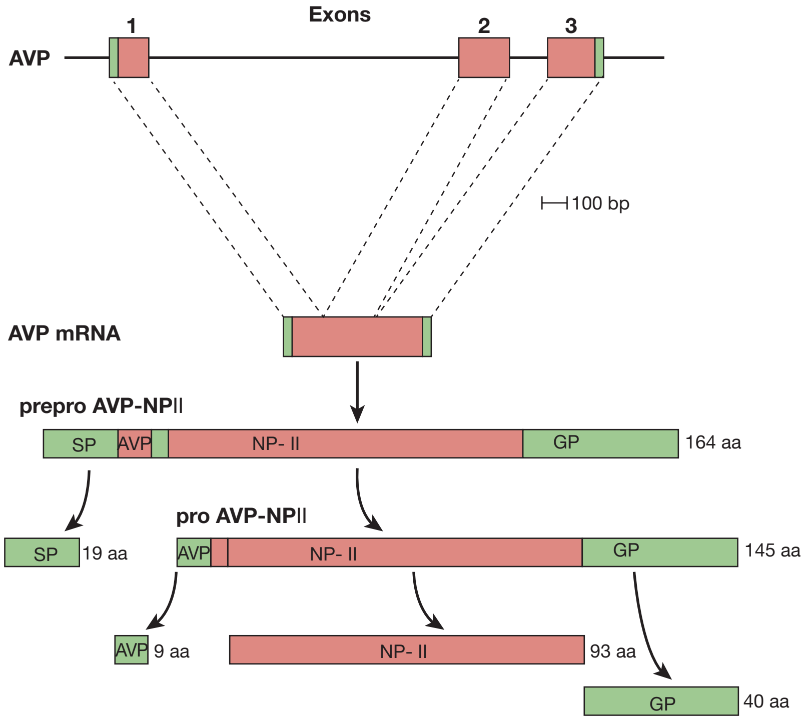

Figure 118-2 Arginine vasopressin. The three exons of the human AVP gene rise to a 700-base arginine vasopressin mRNA. The mRNA is translated into a 164-amino-acid (aa) preprohormone with a 19-aa amino terminal signal peptide (SP). The SP is cleaved, giving rise to a 145-aa prohormone. This prohormone is processed into the nonapeptide AVP, a 93-aa neurophysin (NP), and a 40-aa glycoprotein (GP). The black line divisions in each box represent the protein-coding portions of the gene and mRNA.

as the *syndrome of inappropriate antidiuretic hormone* (SIADH). Up to one-third of patients with lung cancer and hyponatremia do not demonstrate elevation of AVP in their tumors or plasma.[31–33] In these patients, the ectopic production of atrial natriuretic peptide (ANP) has been implicated, but the exact contribution of this hormone remains to be defined.[31]

■ Biology

AVP is a nine-amino-acid peptide normally produced by the neurohypophysis. The peptide binds to receptors in the kidney to reduce the excretion of free water. When plasma osmolality exceeds 280 mOsm/kg, the release of AVP from the pituitary increases, causing the kidney to retain more free water and maintain fluid and osmolar balance. In patients with SCLC, ectopic production of AVP causes hyponatremia by inhibiting free-water excretion in the distal tubule of the kidney. AVP mRNA is expressed in SCLC cells and the peptide is translated and secreted (Fig. 118-2). Measured levels of AVP in plasma are often increased.[34]

There is a subgroup of patients with SCLC and hyponatremia, however, who have no detectable levels of plasma AVP.[35] Similar findings have been shown in SCLC cell lines.[36] The tumors from these patients express ANP mRNA and secrete the peptide, resulting in high levels of circulating ANP in plasma.[37] ANP is the leading candidate to be the natriuretic factor that Bartter and Schwartz proposed in their original description of SIADH. Further investigation into the precise role of ANP in patients with SCLC and hyponatremia of malignancy is ongoing.

■ Diagnosis

In patients with lung cancer, hyponatremia is most frequently diagnosed as a laboratory abnormality in the absence of significant symptoms. The symptoms of acute hyponatremia do not typically occur because the syndrome develops over a prolonged period in concert with the growth of the lung cancer. When symptomatic, mild hyponatremia (serum sodium <135 mmol/L) can cause headache, difficulty concentrating, nausea, weakness, and fatigue. Severe hyponatremia (serum sodium <125 mmol/L), especially when it develops rapidly, can lead to serious symptoms including confusion, hallucinations, seizures, coma, respiratory arrest, decerebrate posturing, and death.[38]

The diagnosis of SIADH is based on the following criteria: (1) plasma hypo-osmolality (<280 mOsm/kg); (2) osmolality of urine greater than serum (usually >500 mOsm/kg); (3) persistent urinary excretion of sodium in the absence of diuretics (>20 mEq/L); (4) absent signs of volume depletion; and (5) normal renal, adrenal, and thyroid function.[39]

In patients with lung cancer, nonmalignant causes of hyponatremia should be considered in the initial evaluation. These include diuretic use, renal disease, cardiac dysfunction, hypoadrenalism, thyroid disease, and dilutional hyponatremia. Medications as a cause for hyponatremia also should be addressed. Patients with lung cancer are commonly treated with cisplatin, selective serotonin reuptake inhibitors, and narcotics, which can cause SIADH.

■ Treatment

The initial therapy for hyponatremia caused by lung cancer is treatment of the underlying malignancy. This often involves multimodality therapy with surgical excision, radiation, and/or chemotherapy. Even with tumor response to therapy, hyponatremia often persists or may recur following tumor progression. In SCLC, there are data to suggest that those patients who do not fully regain normal values of plasma sodium have a poorer survival than those patients who do.[40,41]

Asymptomatic patients with chronic hyponatremia are at low risk for serious neurologic sequelae but are at risk of developing osmotic demyelination with rapid correction of the serum sodium concentration.[42] Treatment is therefore aimed at gradual correction. Fluid restriction, which can be estimated by urinary and plasma electrolytes, but is usually started at 500 mL per day, is a cornerstone of therapy.[43] Pharmacologic therapy may be indicated when fluid restriction is ineffective or poorly tolerated. Demeclocycline blocks the action of AVP on the renal tubule, thereby reducing urine osmolality and increasing serum sodium levels; however, its effects can be variable, and it can cause nephrotoxicity.[38] Lithium and phenytoin also inhibit the effects of AVP on the renal tubule but are no longer recommended for treatment. A more recent option for the treatment of hyponatremia is vasopressin receptor antagonists. Conivaptan is a nonselective vasopressin receptor antagonist indicated for patients with moderate to severe hyponatremia with no severe symptoms and is administered intravenously.[44] Tolvaptan is an orally active, selective AVP receptor 2 (V2) antagonist that has a similar indication. By blocking AVP effects in the renal collecting duct, aquaresis is promoted, leading to a controlled increase in serum sodium levels.[45]

For patients who present with severe, symptomatic hyponatremia characterized by seizure, delirium, or coma, rapid treatment is warranted.[46] The widely accepted goal of therapy is to correct the serum sodium by 1 to 2 mmol/L per hour through the infusion of 3% saline. The administration of concomitant furosemide also is recommended. The magnitude of correction within the first 24 h is suggested to be no more than 8 to 10 mmol/L and no more than

18 to 25 mmol/L in the first 48 h to avoid osmotic demyelination. An alternative approach is to treat until acute symptoms resolve and then adjust the correction rate.[47]

ECTOPIC ADRENOCORTICOTROPIC HORMONE (ACTH) SYNDROME

Lung cancers are the most common neoplasms that cause ectopic ACTH production and Cushing syndrome, accounting for 50% of all cases. SCLC accounts for 80% to 90% of cases associated with lung cancer. Carcinoid tumors (10%) and bronchial adenocarcinomas (5%) also have been reported to produce biologically active ACTH. While biochemical abnormalities suggestive of ectopic ACTH production are reported in 30% to 50% of SCLC, Cushing syndrome is clinically present in only 1% to 5% of SCLC.[48–53] Hypercortisolism is important to recognize as it increases the risk of therapy-induced complications[54,55] such as opportunistic infections and venous thromboembolism (VTE).[56–58]

Biology

Most cases of Cushing syndrome associated with lung cancers are caused by ectopic production of ACTH by the tumor.[59] The precursor gene, proopiomelanocortin (POMC), is expressed in the cancer cells, and a 241-amino-acid prohormone is translated and then cleaved into ACTH (39 amino acids), melanocyte-stimulating hormone, and opiate-like hormones (Fig. 118-3). The ACTH binds to receptors in the adrenal gland, causing them to produce excessive glucocorticoid and mineralocorticoid hormones.[60]

Ectopic production of corticotropin-releasing hormone (CRH) has been reported as a cause of Cushing syndrome in a small number of patients with SCLC or bronchial carcinoids.[52] CRH is a 41-amino-acid peptide normally produced in the paraventricular nuclei of the hypothalamus that stimulates the release of ACTH from the pituitary.

Clinical Presentation and Diagnosis

Ectopic ACTH production occurs with equal frequency in males and females, but Cushing syndrome has an 8:1 female preponderance. Patients who have slow-growing carcinoid tumors often present with the clinical features of Cushing syndrome: truncal obesity, moon facies, striae, polyuria, and polydipsia. In contrast, patients with SCLC often present with other signs of mineralocorticoid and glucocorticoid excess due to the rapidity of tumor growth: edema, weakness, hypertension, and hypokalemic alkalosis.

The diagnostic evaluation of ectopic ACTH syndrome starts by excluding iatrogenic Cushing syndrome in order to avoid unnecessary chemical testing. Once iatrogenic disease has been excluded, initial testing should include the following: 24-h urinary free cortisol, late-night salivary cortisol, and the low-dose dexamethasone suppression test.[61–64] The diagnosis of Cushing syndrome is established when at least two of these tests are unequivocally abnormal. Demonstration of an increased plasma ACTH level (>22 pg/mL) confirms that the hypercortisolism is ACTH-dependent. Finally, persistently elevated serum cortisol in response to a high-dose dexamethasone suppression test differentiates ectopic ACTH syndrome from a pituitary source (high-dose dexamethasone will suppress pituitary but not ectopic source of ACTH).[61,65,66] Bronchial carcinoids are an exception, because in some tumors ACTH and cortisol levels have been suppressed by dexamethasone.[67,68]

In patients with clinical features of Cushing syndrome in whom the dexamethasone suppression test is equivocal, a CRH stimulation test or bilateral inferior petrosal vein sampling will provide the definitive diagnosis. After CRH infusion, pituitary tumors release increased amounts of ACTH, whereas pituitary-independent lung tumors should not. Similarly, in pituitary-dependent Cushing syndrome, petrosal vein sampling will reveal a gradient between the level of ACTH in the petrosal vein and the peripheral concentration. In contrast, patients in whom ACTH is ectopically produced demonstrate no gradient between the petrosal vein and the peripheral blood.[69,70]

Treatment

Management of a patient with lung cancer and ectopic ACTH syndrome requires therapy directed at both the underlying tumor and the hypercortisolism. The treatment for a patient with ectopic ACTH production is to remove the source of the ACTH. This requires combination chemotherapy, with or without irradiation, for patients with SCLC and surgical resection and/or radiation for patients with carcinoid tumors. Chemotherapy for patients with SCLC and ectopic ACTH syndrome has been problematic. Patients often have a poor response to chemotherapy and are susceptible to

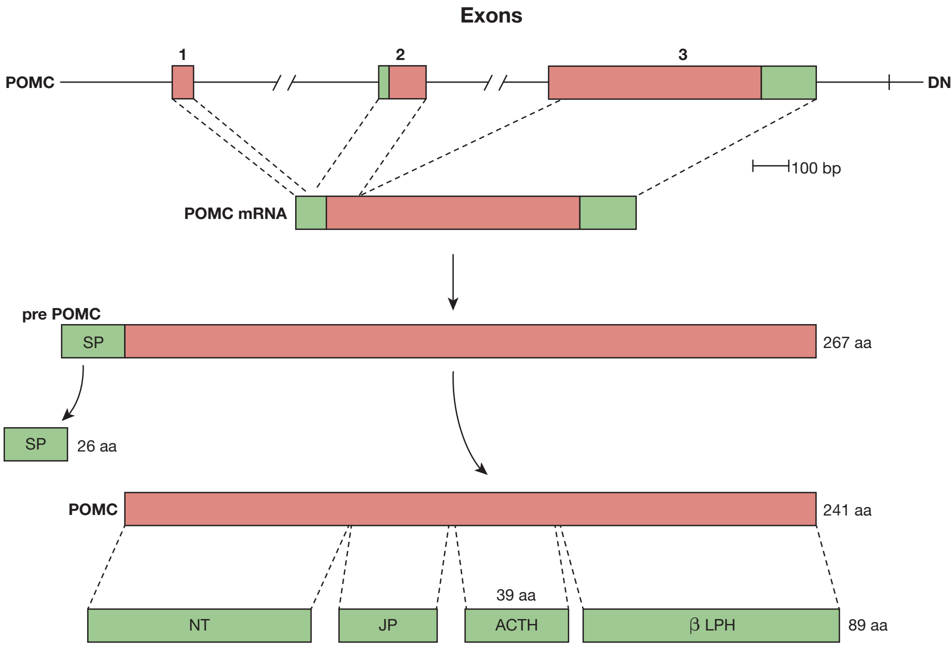

Figure 118-3 Proopiomelanocortin. The three exons of the POMC gene give rise to a 1072-base POMC mRNA. The mRNA is translated into a 267-amino-acid pre-POMC with a 26-amino-acid amino terminal signal peptide (SP). The SP is cleaved, creating the 241-amino-acid POMC. The POMC peptide is cleaved into many products, including the N-terminal peptide (NT), the joining peptide (JP), a 39-amino-acid mature ACTH, and β-lipotropin (β-LPH). The molecules can also undergo further processing. The black portions of the exons represent the protein-coding portion of the gene and mRNA.

early infection and death. Early control of a patient's glucocorticoid excess is beneficial and may reduce the morbidity of treatment.

When removal of the ectopic source of ACTH is not possible, pharmacologic agents directed at blocking adrenal cortisol production may be successful. These drugs include ketoconazole, mitotane, metyrapone, and aminoglutethimide. Ketoconazole is an imidazole derivative that inhibits steroidogenesis at both adrenal and gonadal sites; it may be the most effective and least toxic agent available.[71,72] Metyrapone and aminoglutethimide also have shown limited success by inhibiting adrenal steroid synthesis. Octreotide, a somatostatin analogue, can suppress ectopic ACTH production and has been reported to be useful in some of these patients.[71] Bilateral adrenalectomy should be considered in patients who fail medical therapy.[65,73]

In some patients, the clinical signs and symptoms of ectopic ACTH production develop before the development of a clinically obvious lung cancer. In these cases, symptomatic management of hypercortisolism is undertaken and periodic imaging studies are performed because these patients may have a slow-growing carcinoid tumor that will be amenable to surgical resection.[67,74]

ACROMEGALY

Only 1% of acromegaly is caused by ectopic production of growth hormone–releasing hormone (GHRH) or growth hormone (GH) by tumors.[75] Of these, the majority are caused by carcinoid tumors of the lung and intestine.[76]

Biology

The ectopic production of GHRH or GH by lung cancers has been demonstrated to cause acromegaly. In most cases, the GHRH gene is expressed by the cancer cells, and a 40- or 44-amino-acid peptide is produced.[77] Circulating GHRH peptide binds to receptors in the pituitary gland resulting in the production of excessive amounts of GH.[78] GH then mediates its effects through GH receptors in soft tissue and by stimulating the production of insulin-like growth factor 1 (IGF-1).

Although many carcinoid tumors express immunoreactive GHRH and result in abnormal GH secretion,[79–81] most patients with these tumors are not clinically acromegalic. It has been suggested that the observed high incidence of GHRH expression and low incidence of clinical acromegaly may be due to inadequate tumor production of GHRH or due to the impaired bioactivity of the circulating GHRH.[78]

Diagnosis

The earliest features of GH excess are hypertrophy of the extremities and face (often manifest as increased glove, shoe, and ring size), thickened leathery skin, prominent skin folds, hyperpigmented skin, and hair growth. Bony changes, hypertension, and diabetes mellitus are later, less common findings.

The presentation of a patient with a lung mass and signs of acromegaly should raise suspicion of ectopic acromegaly especially if the mass is found to be carcinoid. The diagnosis of ectopic acromegaly is established by elevated serum levels of GHRH or GH, the absence of a pituitary tumor, complete recovery following lung tumor resection, positive GHRH immunostaining, detection of GHRH mRNA, positive bioassay (cultured rat pituitary cells produce GH in response to tumor extract), or GHRH extraction from the tumor tissue.[82] Because coincidental pituitary tumors and solid tumors have been described, patients who have lung cancer in association with low GHRH levels and high GH and IGF-1 levels should undergo magnetic resonance imaging (MRI) to exclude a pituitary tumor.

Treatment

Management of ectopic acromegaly involves surgical resection of the tumor and is often curative in those with lung carcinoid. In those with unresectable or metastatic cancers, medical therapy with somatostatin analogues, such as octreotide and bromocriptine, has been shown to be effective.[83,84] Bromocriptine acts by inhibiting GH release by the pituitary; octreotide lowers both GH and IGF-1 levels in plasma and also appears to inhibit GHRH release by tumors. Clinical abatement of acromegalic features has been reported in patients treated with octreotide.

CARCINOID SYNDROME

Ectopic serotonin production is rare in lung neoplasms, occurring in 1% to 5% of patients with pulmonary neuroendocrine tumors (NETs).[85] Hallmarks of the syndrome include flushing of the skin of the upper thorax, secretory diarrhea, and bronchoconstriction. It is important to recognize an acute carcinoid crisis in patients with lung cancer as it can be precipitated by chemotherapy, biopsy, anesthesia, surgery, or the use of adrenergic drugs. It is a result of a massive serotonin release and can lead to cardiopulmonary failure.[86]

The evaluation for carcinoid syndrome begins with a 24-h urine collection for the main metabolite of serotonin, 5-hydroxyindoleacetic acid (5-HIAA). This test has a specificity of approximately 90%.[87] Detection of occult NETs in patients presenting with a carcinoid syndrome may be aided by testing for serum biomarkers of NETs such as neuron-specific enolase (NSE) and chromogranin A.[88] When these serum biomarkers are negative in a patient with high clinical suspicion of a NET, radionuclide-labeled octreotide scintigraphy is useful as up to 80% of pulmonary NETs express somatostatin receptors.

In patients who are surgical candidates, surgery is the optimal treatment of carcinoid syndrome. Otherwise, control of symptoms should be the goal via somatostatin analogues, serotonin receptor blockers, interferon, and antidiarrheal medications. In addition, carcinoid crisis can be prevented or treated with intravenous octreotide acetate.[86]

HEMATOLOGIC SYNDROMES

Most hematologic syndromes associated with lung tumors are not as well characterized as the endocrine syndromes, and an ectopic hormone responsible for the syndrome has not been identified in most tumor tissues. In many of the hematologic syndromes, such as granulocytosis and thrombocytosis, clinical sequelae are often absent. As with the endocrine paraneoplastic syndromes, the most appropriate therapy for the hematologic syndromes is the treatment of the underlying neoplasm.

Granulocytosis

NSCLC is the most common cancer associated with granulocytosis. Some 15% to 20% of patients with NSCLC have granulocytosis, with absolute white blood counts ranging from 10,100 to 25,000 (normal range, 4000–10,000). Its presence is associated with a poorer prognosis compared to patients without granulocytosis.[89–91] Although granulocyte colony–stimulating activity can be demonstrated in serum and/or urine in 80% of affected patients, tumor production of granulocyte colony–stimulating factor, granulocyte-monocyte colony–stimulating factor, or interleukin 6 (IL-6) has been shown in only a minority of patients.[92,93]

Virtually all patients with lung cancer who present with tumor-associated granulocytosis are asymptomatic from the excess white blood cells. The diagnosis is suggested by the presence of an increased white blood count in which neutrophils predominate without immature forms, in the absence of nonneoplastic causes. An increased leukocyte alkaline phosphatase score and a normal bone marrow are consistent with this diagnosis.

Thrombocytosis

Thrombocytosis is common in patients with lung cancer, afflicting 16% to 32% of patients with both NSCLC and SCLC.[94,95] The pathogenesis of thrombocytosis in patients with lung cancer has not been definitively elucidated. IL-6, which is a cytokine for megakaryocytes, has been demonstrated in cell lines from patients with lung cancer and thrombocytosis, and increased levels of IL-6 have been demonstrated in the plasma of such patients. Thrombopoietin is increased in patients with lung cancer and thrombocytosis but is decreased in patients with essential thrombocytosis. The identification of the thrombopoietin gene may lead to a better understanding of the role of this protein in paraneoplastic thrombocytosis.

Patients with thrombocytosis are nearly always asymptomatic and do not have an increased incidence of thromboembolism. The diagnosis of cancer-associated thrombocytosis is suggested by an increased platelet count (>500,000/mm^2) in a patient with newly diagnosed lung cancer, and it is associated with advanced disease and worse clinical outcomes.[96,97] A primary myeloproliferative disorder can be excluded by a bone marrow biopsy.[98] In addition, the presence of the JAK2 V617F mutation may indicate essential thrombocytosis (present in 50% of cases) since it is not present in cases of reactive thrombocytosis.[99]

■ Thromboembolism

Of all disease states, lung cancer is known to have one of the strongest associations with VTE.[100] The incidence of VTE in patients with lung cancer is approximately 40 to 100 cases per 1000 person-years compared to 1 to 2 cases per 1000 person-years in the general population. It is also notable that 20% of patients who present with recurrent idiopathic venous thrombosis are found to have an underlying diagnosis of cancer.[101] The spectrum of causes of thrombosis in patients with lung cancer is broad, including disseminated intravascular coagulation (DIC), Trousseau syndrome (recurrent migratory venous thrombophlebitis), nonbacterial thrombotic endocarditis, and obstruction of great vessels.[102,103] Surgical procedures and chemotherapy also have been demonstrated to increase risk of thrombotic complications among cancer patients.[104]

Cancer cells are able to directly activate the clotting cascade via two procoagulants: tissue factor and cancer procoagulant. Increased expression of human tissue factor has been shown in NSCLC tissue, and active tissue factor–bearing microparticles, which may originate from tumor cells, have been demonstrated in the circulation of cancer patients.[105,106] Microparticle-associated tissue factor activity has been proposed as a mechanism for the prothrombotic state in cancer patients.[107]

The treatment of VTE associated with active lung cancer differs from standard treatment of VTE as the increased risk of recurrent thromboembolism must be balanced with the increase risk of bleeding. It was previously shown that for recurrent thromboses (as in Trousseau syndrome), long-term subcutaneous heparin is more efficacious than warfarin.[108] A meta-analysis of six randomized controlled trials in cancer patients being treated with long-term anticoagulation for VTE found a statistically significant reduction in VTE with LMWH compared to warfarin, with no significant difference in bleeding.[109,110] In addition, a large multinational randomized controlled trial showed that the direct oral anticoagulant apixaban (without a previous course of heparin) is an effective and safe alternative to dalteparin (an LMWH) for VTE associated with malignancy.[111] LMWH is contraindicated with creatinine clearance <30 mL/min. Direct oral anticoagulants have not been adequately studied in patients with renal insufficiency; dose adjustments and monitoring of anti-factor Xa levels may be necessary if used in this setting.[112]

NEUROLOGIC SYNDROMES

There are a number of paraneoplastic neurologic syndromes associated with lung cancer. Encephalomyelitis, cerebellar degeneration, retinopathy, opsoclonus/myoclonus, and the Lambert–Eaton syndrome have all been described and are most commonly associated with SCLC. The majority of these syndromes are a result of an autoimmune response directed at shared antigens present in both cancer cells and normal neural tissue. The autoantibodies associated with each neurologic syndrome are listed in Table 118-2.

■ Encephalomyelitis/Subacute Sensory Neuropathy

The paraneoplastic syndrome of encephalomyelitis/subacute sensory neuropathy was first described in a patient with SCLC. More than 70% of cases of paraneoplastic encephalomyelitis are diagnosed in patients with SCLC, with a wide range of clinical presentations. A specific antibody, anti-Hu, which reacts with the HuD antigen expressed by lung cancer cells and neuronal tissues, has been identified in many patients who develop this syndrome. Approximately 20% of patients with SCLC are seropositive for anti-Hu, but only a few will develop a paraneoplastic neurologic disorder.[113]

Biology

Anti-Hu is an IgG antibody found in the sera and cerebrospinal fluid of patients with sensory neuropathy and encephalomyelitis. Patients with anti-Hu have an immune response targeting a family of proteins known as Hu, which are expressed in both neurons and SCLC cells. They are RNA-binding proteins involved in the post-transcriptional regulation of RNA in neurons.[114] The *HuD* gene has been mapped to the chromosome 1p region and appears to be a marker of neuroendocrine differentiation in these cells.

Diagnosis

The location and severity of neuronal loss predict the patient's clinical symptoms. Neuronal loss may be limited to one area of the nervous system but more frequently involves multiple areas over time.[34] Onset of symptoms is subacute and precedes the diagnosis of SCLC in greater than 70% of cases, thus warranting a complete diagnostic evaluation for occult malignancy in those presenting with encephalomyelitis or subacute sensory neuropathy. One-half of patients undergo progressive sensory loss in the hands and feet. Others present with a limbic encephalopathy characterized by memory loss, behavioral changes, and seizures. Focal myelopathy with weakness, brain stem signs (nystagmus, dysarthria), and autonomic nervous system dysfunction also occur in patients with this syndrome. CT scans are typically normal in these patients, but MRI studies may show increased T2 signal in affected areas of the brain.

TABLE 118-2 Neurologic Syndromes Associated with Lung Cancer

Syndrome	Tumor	Antibody	Antigen
Encephalomyelitis/subacute sensory neuropathy	Small-cell	Anti-Hu	Hu-D antigen: 35- to 40-kDa neuronal nuclear protein
Cancer-associated retinopathy	Small-cell	Antirecoverin	23-kDa protein specific to photoreceptor cells (recoverin)
Lambert–Eaton syndrome	Small-cell	Anti-P/Q channel	P/Q-type calcium channel

Pathologic examination demonstrates neuronal loss and inflammatory infiltrates in areas of the nervous system including the brain stem, hippocampus, spinal cord, and dorsal root ganglia.[115] Serum and cerebrospinal fluid from patients with paraneoplastic encephalitis will often reveal the anti-Hu antineuronal antibody.

Treatment

Early diagnosis and treatment of the underlying tumor offers the best chance for stabilizing the neurologic syndrome.[116] Alternative therapies with immunosuppressive agents and plasmapheresis, with the goal of clearing the responsible antibody, have been shown to be effective in only 10% to 20% of patients. Patients with anti-Hu positive neurologic paraneoplastic syndromes are more likely to die of neurologic causes including respiratory muscle failure, autonomic failure, and progressive diffuse encephalopathy rather than from metastatic cancer.[117,118]

■ Paraneoplastic Cerebellar Degeneration

Paraneoplastic cerebellar degeneration is manifested by symptoms including ataxia, nystagmus, dysarthria, mental status changes, muscular and sensory deficits, and diplopia. This disorder accounts for 12% of cases of paraneoplastic neurologic syndromes secondary to lung cancer.[119] Pathologically, there is the diffuse loss of Purkinje cells accompanied by thinning of the molecular and granular layers, and degeneration of the long tracts of the spinal cord.[120] In patients with SCLC, paraneoplastic cerebellar degeneration can occur with or without the presence of Hu antineuronal antibodies, indicating that the syndrome can develop via different immunologic mechanisms.[117]

■ Opsoclonus and Myoclonus

Opsoclonus is a disorder consisting of involuntary rapid conjugate eye movements in vertical and horizontal directions. It is often associated with myoclonus in patients with solid tumors. This syndrome of opsoclonus/myoclonus has been identified in both SCLC and NSCLC. Opsoclonus/myoclonus is the main presentation of paraneoplastic cerebellar degeneration associated with anti-Ri antibodies.[121] Anti-Ri binds to two proteins (55 and 80 kDa) expressed in the dentate nucleus.[122] Anti-Ri antibodies have also been identified in those presenting with a broad variety of neurologic symptoms.[123] The anti-Hu antibody has been identified in some patients with SCLC and opsoclonus/myoclonus.

■ Cancer-associated Retinopathy

Cancer-associated retinopathy is a rare paraneoplastic syndrome that occurs predominantly in patients with SCLC. Autoantibodies have been identified in patients with this disorder that bind to a photoreceptor-specific protein called recoverin.[124,125]

Biology

Retinal ganglion cells and their processes are characteristically lost in this disorder because of the autoantibodies that bind to recoverin, a 23-kDa photoreceptor-specific protein found in rods and cones as well as in SCLC cells. The autoantibodies that cause the cancer-associated retinopathy specifically bind to the recoverin protein and do not recognize other retinal proteins.[89,90,126,127]

Diagnosis

The clinical triad of photosensitivity, ring-scotoma visual field loss, and attenuation of retinal arteriole caliber is considered highly suggestive of cancer-associated retinopathy. The typical patient presents with symptoms of rapid visual loss, night blindness, and color loss. On physical examination, most patients demonstrate visual field deficits, disk pallor, and cells in the vitreous body, along with arteriolar narrowing.

Demonstration of the anti-recoverin antibody in a patient with signs of retinopathy establishes the diagnosis. As with paraneoplastic cerebellar degeneration, cancer-associated retinopathy is often the first sign of an occult carcinoma. Therefore, an evaluation for lung cancer should be performed in all patients who present with this syndrome.[91,128,129]

Treatment

In contrast to those with the other paraneoplastic neurologic syndromes, more than half of patients with cancer-associated retinopathy have been reported to respond with visual improvement after systemic steroid therapy. Treatment of the primary tumor without immunosuppressive therapy has not been shown to result in visual improvement in patients with cancer-associated retinopathy, and most of these patients develop progressive visual loss and blindness within 18 months.[130]

■ Lambert–Eaton Syndrome

The Lambert–Eaton syndrome afflicts fewer than 2% of lung cancer patients but has been reported in up to 5% of patients with SCLC. Conversely, 50% to 60% of all patients with Lambert–Eaton syndrome will be diagnosed with SCLC.[131]

Biology

Lambert–Eaton syndrome is a consequence of the development of antibodies to P/Q-type voltage-gated calcium channels in motor and autonomic nerve terminals, leading to inhibition of acetylcholine release.[132] The resulting weakening of the neuromuscular signal results in neurologic dysfunction. This antibody also binds to the 58-kDa synaptic vesicle protein synaptotagmin, which is present in SCLC cells.[133] These antibodies have been detected in 85% to 90% of patients with Lambert–Eaton syndrome and some reports cite close to 100% detection in those with SCLC.[134]

Diagnosis

Lambert–Eaton syndrome is diagnosed based on clinical signs and symptoms, electrophysiologic studies, and antibody testing. The classic clinical triad is proximal muscle weakness (usually the first symptom noted), autonomic dysfunction, and areflexia.[135] While symmetric muscle involvement is most common, some patients present with isolated weakness (e.g., only proximal legs, isolated limb, ocular, oropharyngeal, or respiratory muscles).[136,137] Physical examination reveals decreased or absent tendon reflexes. Because there is a short-term return of reflexes following muscle contraction in 40% of patients, these should be tested after a period of rest.[138] Electrophysiologic studies with repetitive nerve stimulation are often diagnostic of Lambert–Eaton syndrome. A decrement in the amplitude of the muscle action potential of at least 10% is considered abnormal, a finding seen in the overwhelming majority of patients with Lambert–Eaton syndrome. Nerve stimulation after exercise demonstrates an amplitude increase, which has a high sensitivity and 100% specificity for Lambert–Eaton syndrome and distinguishes this entity from myasthenia gravis.[139,140]

Treatment

Treatment of the underlying SCLC with chemotherapy often can effectively treat Lambert–Eaton syndrome. Should symptoms persist, the first choice of treatment is 3,5-diaminopyridine, which results in functional improvement the majority of the time. There are two proposed mechanisms of action. First, by blocking voltage-gated potassium channels, the action potential at the motor nerve terminals is prolonged and the opening time of the voltage-gated calcium channels is lengthened.[141] Second, neuromuscular transmission is potentiated by targeting a subunit on the voltage-gated

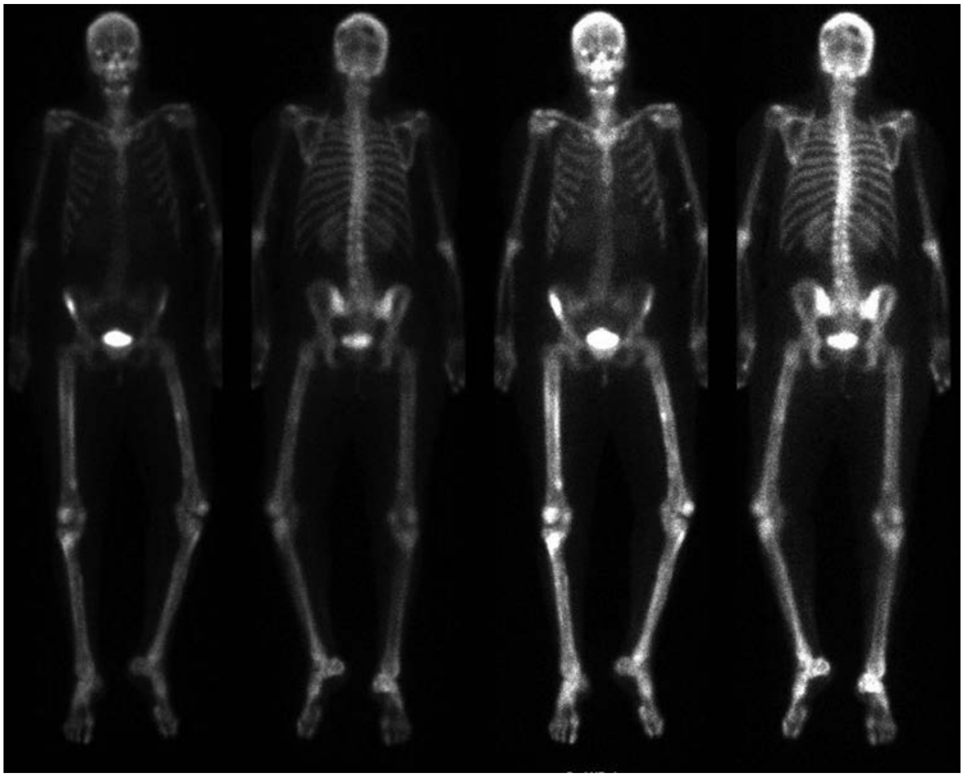

Figure 118-4 Tc99 bone scintigraphy reveals symmetric diffusely increased uptake mainly along the cortical margins of both femurs (seen best in the two delayed phase images on the right).

calcium channel directly.[142] In those with severe weakness and impairment that develops gradually over time and fails to improve despite treatment of the underlying cancer and a trial of 3,5-diaminopyridine, combined therapy with prednisone and azathioprine has been shown to be effective.[143] For those with severe weakness and severe impairment that develops rapidly, treatment with intravenous immunoglobulin or plasmapheresis is indicated as it can provide marked, albeit transient, improvement in strength while treatment for SCLC is started.[144]

HYPERTROPHIC PULMONARY OSTEOARTHROPATHY

HPO is characterized by the abnormal proliferation of the cutaneous and osseous tissues at the distal parts of the extremities. While any intrathoracic malignancy may be associated with HPO, the disease is secondary to primary lung cancer in 80% of cases.[145] HPO is estimated to occur in 0.7% to 4.5% of patients with lung cancer.[145–148]

■ Biology

While the exact mechanisms of HPO have not been elucidated, there are a number of theories. One theory suggests that arteriovenous shunting within the tumor allows platelet clumps and megakaryocytes that are usually cleared by the pulmonary endothelium to enter the systemic circulation and deposit in the distal vasculature, causing the local release of growth factors including platelet-derived growth factor (PDGF) and vascular endothelial growth factor (VEGF).[149] PDGF causes proliferation of fibroblasts and an increase in vascularity and permeability resulting in connective tissue changes that are the hallmark of clubbing.[150] VEGF leads to vascular hyperplasia, osteoblastic differentiation with new bone formation, and edema; all are features of HPO.[151] Ectopic production of these growth factors by the lung cancer is an alternative hypothesis.[152] Finally, there is a neurogenic hypothesis that proposes a vagally-mediated alteration in limb perfusion. This is supported by experimental and clinical observation of resolution of HPO symptoms following unilateral vagotomy.[153]

■ Diagnosis

Diagnosis of HPO is based on clinical symptoms, physical examination, and radiographic findings. The classic triad consists of digital clubbing, arthritis, and bilateral, symmetrical periosteal formation of new bone. The latter finding is often present on plain films of the long bones but bone scintigraphy is the most sensitive method for the detection and evaluation of the extent of HPO-associated periostitis (Fig. 118-4). With its ability to delineate the subtleties of the disease, scintigraphy often reveals abnormalities that precede plain radiograph changes.[154] Scintigraphy findings range from symmetrical increased "bracelet-like" uptake to diffuse uptake in the juxta-articular regions and distal portions of the long bones.[155] There are case reports documenting the ability of fluoro-18-deoxyglucose positron emission tomography (PET) to detect periosteal new bone formation of HPO and it is more sensitive and specific than bone scintigraphy for detecting bone metastasis as an alternative cause of long bone pain.[156–158]

■ Treatment

With resection and/or treatment of the primary tumor, the symptoms of HPO will improve and often resolve completely.[148,159,160] When the primary tumor cannot be eliminated, there are a variety of symptomatic treatments for HPO, based largely on the postulated pathogenetic mechanisms, that anecdotally have been demonstrated to be effective.[161] Performance of unilateral vagotomy on the ipsilateral tumor side has led to complete resolution of pain and radiographic regression of HPO.[162,163] There are a number of case reports to support the use of nonsteroidal anti-inflammatory drugs including ketorolac, indomethacin, and the COX-2 inhibitor rofecoxib.[149,164,165] Prostaglandin E is effectively reduced with these medications, thereby decreasing periostitis and HPO symptoms. The somatostatin analogue octreotide has also been used with success in

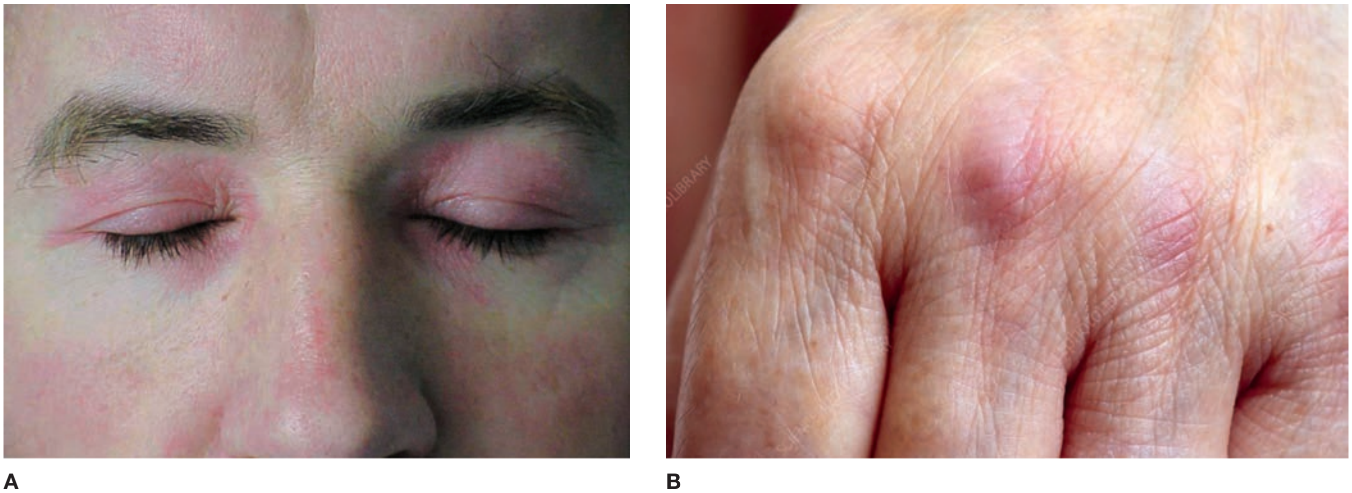

Figure 118-5 Dermatomyositis periorbital heliotrope rash and Gottron's papules on hands. *(**A.** Reproduced with permission from Jaeschke R, Gajewski P, O'Byrne PM: McMaster Textbook of Internal Medicine 2019/20. Kraków, Poland: Medycyna Praktyczna; 2019. **B.** SPL/Science Source.)*

the treatment of HPO and is thought to be efficacious due to inhibition of VEGF and endothelial proliferation.[166,167] Bisphosphonates are potent inhibitors of bone metabolism and also decrease the levels of VEGF, and symptomatic improvement has been demonstrated with both pamidronate and zoledronic acid.[168,169]

INFLAMMATORY MYOPATHIES

Polymyositis (PM) and dermatomyositis (DM) are autoimmune inflammatory myopathies that can manifest as paraneoplastic syndromes in the setting of lung cancer, though they are more common in association with other malignancies.[1] DM has a stronger association than PM with malignancy and about 10% to 25% of cases are paraneoplastic.[170,171] SCLC is more commonly associated with DM.[172–174] Painless proximal muscle weakness is a hallmark. DM is associated with a heliotrope rash (purple periorbital discoloration), Gottron papules (purple papules and plaques on the dorsum of both hands) and erythematous rash on the face, neck, back, chest, and shoulders (Fig. 118-5).[175] The diagnosis of DM is suggested by an elevated level of creatine phosphokinase, characteristic findings on electromyography, and muscle biopsy findings demonstrating a mixed B- and T-cell perivascular inflammatory infiltrate and perifascicular muscle fiber atrophy.[176] The mainstay of management of these syndromes consists of cancer-directed therapy. Standard treatments of inflammatory myopathies may also be necessary, such as high-dose glucocorticoids or other immunosuppressive medication. In general, these syndromes are less responsive to immunosuppressive medications than when not paraneoplastic.[177]
